reported perinatal mortality rates as high as 30–70% (Allen et al. 2001) but in cases diagnosed during the second trimester the mortality rate is probably much lower – about 10%. Nevertheless, MA twins represent a serious and shared challenge to obstetricians and neonatologists in balancing the risk of intrauterine death against the complications associated with preterm delivery. The primary cause of fetal death is cord compression as a result of cord entanglement. There have been no randomised trials on the management of MA pregnancies but protocols include intensive ultrasound surveillance, sulindac to reduce amniotic fluid volume and delivery by planned caesarean delivery at 32 weeks' gestational age (Pasquini et al. 2006). Superficial vascular anastomoses are common in MA pregnancies (Bajoria 1998) and twin–twin transfusion syndrome (TTTS) is rare.

Conjoined twins

Conjoined twins occur in approximately 1/50 000 pregnancies (Zake 1984). They are a form of MZ twinning in which the division of the zygote is incomplete. The increased incidence of additional unrelated malformations suggests that conjoined twinning may be associated with a fundamental disturbance of embryogenesis (Edmonds and Layde 1982). The factors associated with conjoined twinning are female sex (Milham 1966; Benirschke and Kim 1973; Zake 1984), triplet sets with an MA pair (Schinzel et al. 1979) and it may be more common in parts of Africa (Zake 1984). Seasonal clustering has also been reported (Milham 1966). The site and extent of the fusion are highly variable. Thoracopagus is the commonest form and accounts for about 70% of cases (Rudolph et al. 1967; Edmonds and Layde 1982). Inevitably ethical dilemmas arise with conjoined twins, particularly when surgical separation means that preserving the life of one is likely to be at the expense of the other (Reijal et al. 1992).

Monochorionic, diamniotic twins

MCDA twins have an additional risk to other twin pregnancies, namely the complication of TTTS (Ch. 9). All monochorionic placentas have vascular anastomoses between the two fetal circulations: intertwin transfusion is therefore a normal event. It is only when this transfusion becomes unbalanced, i.e. with net transfer of blood from one twin (donor) to the other (recipient), that TTTS occurs. This haemodynamic imbalance in the parenchymatous arteriovenous network is associated with an absence of superficial anastomoses (Bajoria et al. 1995). Acute TTTS results from an acute haemodynamic imbalance across the superficial arterioarterial or venovenous anastomoses. It is less common than chronic TTTS and tends to occur during labour, when it can cause severe hypovolaemia in the donor and hypervolaemia in the recipient (Fig. 23.4). However, the most common presentation of TTTS is chronic. It complicates, to a varying degree, up to a third of monochorionic pregnancies and is the cause of up to 20% of perinatal mortality in twins. In the past, the diagnosis was made on the neonatal criteria of an intrapair cord blood haemoglobin difference of 5 g/l and birthweight discrepancy. It is now recognised that, in the more severe cases, presenting in the second trimester, these differences are usually absent and the main problems for the recipient fetus are severe polyhydramnios, cardiac hypertrophy, tricuspid regurgitation, venous overload and hydrops and, for the donor, oligohydramnios, sometimes resulting in a 'stuck' twin (Wee and Fisk 2002).

The diagnosis of TTTS is based on amniotic fluid discrepancy measured as the maximum vertical cord free pool using ultrasound.

The criteria for diagnosis are that the deepest pool in the recipient sac is greater than 8 cm and less than 2 cm in the donor sac. Thereafter, the condition is staged based on further ultrasonic criteria and the system described by Quintero et al. (1999) is in widespread use:

stage I: bladder of donor visible

stage II: bladder of donor is not visualised for 1 hour but the

Doppler is normal

stage III: Doppler abnormalities

stage IV: hydrops is present

stage V: demise of one or both twins.

In the newborn, the recipient twin is characteristically heavier and polycythaemic and faces the complications of high blood viscosity, such as cardiac failure, hyperbilirubinaemia and intravascular thromboses, whereas the donor shows signs of intrauterine growth retardation, anaemia and hypoproteinaemia. Renal failure and/or renal tubular dysgenesis due to chronic renal hypoperfusion in utero may also occur (Kriegsmann et al. 2000). When anaemia is the presenting feature, care must be taken to distinguish from other causes of anaemia such as fetomaternal haemorrhage. Hypovolaemia in the donor leads to activation of the renin–angiotensin system, which has trophic effects on vascular smooth muscle. Postnatally, the treatment of the polycythaemic or anaemic twin is similar to singletons with the same problems (Ch. 30). In addition, the recipient may have short- and long-term cardiovascular problems (Karatza et al. 2002). The risk of congenital heart disease is 15–23 times higher in twins affected by TTTS, typically pulmonary stenosis and atrioventricular defects. With the vascular and blood volume changes in TTTS the recipient twin is at risk of increased blood pressure and right heart disease (ventricular hypertrophy/cardiomyopathy, atrioventricular valvar regurgitation and right ventricular outflow obstruction) (Bahatiar et al. 2007). Right ventricular outflow obstruction may become severe enough to require valvotomy in infancy.

There is a relatively high risk of brain damage, often due to periventricular leukomalacia, in TTTS whether or not the donor twin dies, although the risk is undoubtedly increased when there is intrauterine death of one twin. The risk of necrotising enterocolitis is also increased (Hack et al. 2008).

The obstetric management of TTTS is discussed in detail in Chapter 9 (El and Ville 2008).

Postnatal determination of zygosity

Like-sex DZ twins can only be distinguished reliably from the one-third of MZ twins who have dichorionic placentas by DNA analysis. The minisatellite probe test is a highly reliable tool (Hill and Jeffreys 1985), requiring only small quantities of blood or other tissues. Tests are most practically done on placental samples at delivery or on cheek swabs taken from infants or children. Cord blood is frequently used but great care is required to avoid contamination with maternal blood. Blood groups or other genetic markers such as red cell enzymes, serum proteins and tissue enzymes (in particular from the placenta) have all been used for determining zygosity but DNA analysis has now become the standard method. The steps to determine zygosity in newborn twins are shown in Figure 23.3 (Multiple Births Foundation 1997).

Fetal growth in multiple pregnancy

The growth and development of the twin fetus are affected not only by the same intrauterine factors as the singleton fetus but also by the interaction with the second fetus. At best one fetus must

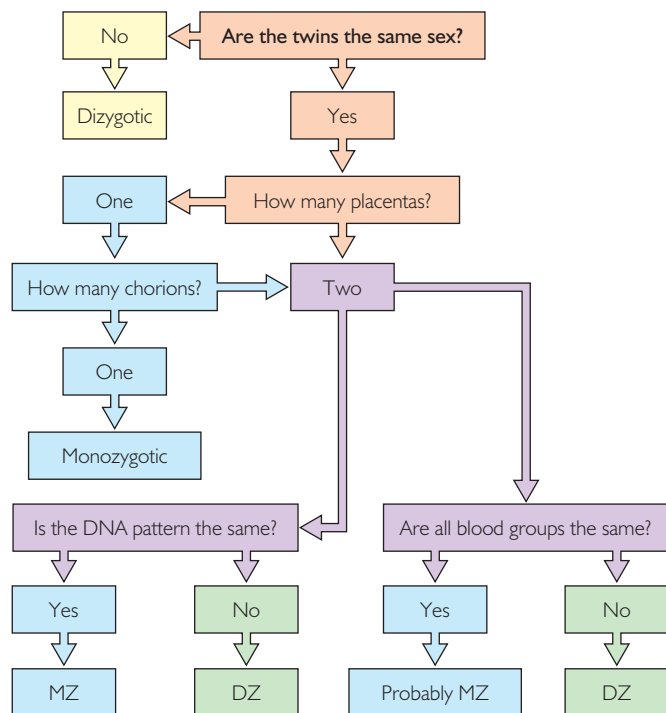

Fig. 23.3 Flow chart for determining zygosity. MZ, monozygotic; DZ, dizygotic.

compete for nutrition, and at worst one twin may be severely, even lethally, damaged by the co-twin (Bryan 1986). Intrauterine growth rates differ between singletons and twins from about 26 weeks, with the divergences then increasing with increasing gestational age (Alexander et al. 1998; Min et al. 2000; Liu and Blair 2002; Hack et al. 2008). As with singletons, primiparous pairs grow more slowly than multiparous (Liu and Blair 2002). The typical pattern of intrauterine growth of twins is similar to that of a growth-retarded singleton in that the weight falls disproportionately more than the occipitofrontal circumference. Birthweight and occipitofrontal circumference centile charts for English twins are now available (Buckler and Green 1994). Some 52% of twins and 92% of triplets are of low birthweight (<2500 g) compared with 6% of singletons, and as many as 10% of twins and 32% of triplets are of very low birthweight (VLBW; <1500 g) (Blickstein 2002). Indeed, twins and triplets contributed at least 35% of the VLBW infants in a population-based study (Blickstein 2002). The average weight of a newborn twin is about 800 g less than a singleton (Liu and Blair 2002) but if allowance is made for differences in gestational age the discrepancy is reduced to 500 g. Opposite-sex twins tend to be heavier than like-sex twins (Liu and Blair 2002), and boys are heavier than girls in both like- and opposite-sex pairs (Liu and Blair 2002). Dichorionic twins tend to be heavier than monochorionic (Ananth et al. 1998) but DZ twins are heavier than both di- and monochorionic MZ twins (Corney et al. 1972). Discordant growth refers to inter-fetal differences in birthweight between the large and small infant, expressed as a percentage of the large twin's weight: its defining value varies from 10% to 25% in different reports. Birthweight discordance may be due to the different sites of implantation of the two placentas or of the umbilical cords, but the commonest cause of large discrepancies in fetal growth is probably haemodynamic imbalance in the chronic form of TTTS (Fig. 23.4). Discordant size during the first half of gestation is likely to be associated with an intrinsic factor such as a malformation (Weissman et al. 1994).

Fig. 23.4 The fetofetal transfusion syndrome, showing intrauterine growth retardation and pallor of the donor (left) and plethora of the recipient.

However, twin pregnancies where the babies are ultimately discrepant for birth weight exhibit difference in growth even as early as 11 weeks' gestational age (Kalish et al. 2003).

Antenatal management

A scheme for the typical antenatal management is outlined in Figure 23.5. When twins are identified, a scan should be requested at around 12 weeks' gestational age by a sonographer who is certified for both determination of chorionicity and measurement of nuchal translucency. Chorionicity is most accurately determined at this gestational age. Moreover, this is within the window for measurement of nuchal translucency to estimate Down syndrome risk. This is important as the serum measurements used to assess Down syndrome risk cannot generally be applied in twin pregnancies. Routine scans are generally scheduled to assess fetal growth and well-being at 4-weekly intervals in DCDA twin pregnancies and 2-weekly intervals in MCDA and MA twin pregnancies. Moreover, many units would offer an earlier anomaly scan in these cases because of the higher frequency of congenital abnormality in MZ twins (see below).

Chromosomal anomalies

These are usually discordant in DZ twins and, surprisingly, also occasionally in MZ twins (Riekhof et al. 1972). The twins are then known as heterokaryotypes and it is assumed that the maldistribution of chromosomes occurred at about the same time as the twinning process. Heterokaryotypes XY/XO are the explanation for the occasional pair of MZ twins of different sexes (Riekhof et al. 1972).

Klinefelter syndrome appears to be more common in twins and in their relatives (Soltan 1968). There also appears to be an increased incidence of Turner syndrome in twins (Carothers et al. 1980) and of twinning among the (normal) family members of patients with Turner syndrome (Nielsen and Dahl 1976). Carothers et al. (1980) suggest that there may be a postzygotic mechanism common to twinning and X-chromosome loss. Genotypic discordance in MZ twins may be caused by a variety of mechanisms (Machin 1996; Gringras and Chen 2001). X inactivation is likely to be the cause of

Fig. 23.5 Overview of antenatal management of twins. CS, caesarean section.

some cases of discordancy for genetic disorders such as Duchenne's muscular dystrophy in MZ twins.

Some anomalies, such as oesophageal atresia (Van Staey et al. 1984) and some cardiac malformations (Burn and Corney 1984), occur more commonly in twins. Cardiac malformations are usually discordant in MZ twins, suggesting that the malformation develops as a result of some process peculiar to MZ twins.

The teratogenic effects of both drugs and intrauterine infections may have intrapair differences in expression (Bryan et al. 1987). This may be because of a difference in fetal susceptibility. In other instances where the teratogenic effect of the drug is sharply limited, as in the case of thalidomide, the discordance could be due to the insult acting at the very beginning or end of the sensitive period. As DZ twins can be conceived several days apart, one embryo may be a few days retarded or accelerated in development and therefore escape unscathed.

Congenital anomalies

In most, though not all, studies a higher prevalence of anomalies has been found among multiple births than among singletons (Little and Bryan 1988). Factors that may cause this apparent variation include the gestational criterion used for defining stillbirth, the range of anomalies studied, opportunities for and thoroughness of examination, twinship itself, maternal age and zygosity distribution.

The increase is limited to MZ twins (Corney et al. 1983). Concordance rates vary considerably by type of anomaly but in general discordance is more common even among MZ twins (Little and Bryan 1988). The less favourable environment of a monochorial placentation accounts for some, but not all, of the increase seen in MZ twins (Melnick and Myrianthopoulos 1979; Corney et al. 1983).

Congenital anomalies in twins pose additional dilemmas. Not only may some conditions be treated antenatally but the possibility

of selective feticide, when one twin has an irremediable anomaly, provides a new and difficult choice for both obstetricians and parents (Bryan 2004).

Anomalies unique to multiple conception

Anomalies unique to the twinning process include conjoined twinning, fetus in fetu, acardia and fetus papyraceus.

Twin reversed arterial perfusion

Twin reversed arterial perfusion, previously known as acardia or chorioangiopagus parasiticus, occurs in about 1/30 000–35 000 deliveries (Gringras and Chen 2001). It varies in its manifestations from a mass of amorphous tissues to an incomplete but otherwise well-formed fetus. An imbalance in the interfetal circulation resulting in atrophy of the heart or a primary failure of cardiac development has been suggested as the aetiological mechanism. As survival of the acardiac fetus is dependent on a shared circulation with the (usually normal) co-twin, twin reversed arterial perfusion occurs only in monochorionic, and therefore MZ, pregnancies. Relatively little attention has been paid to the pump twin. They appear to have a surprisingly high incidence of malformations (Schinzel et al. 1979) but, even when potentially normal, these babies have a high mortality rate of up to 50%, usually as a result of the combination of intrauterine cardiac failure and prematurity (Van Allen et al. 1983). The size of the acardiac twin relative to the pump twin appears strongly to influence the perinatal outcome, with a significantly higher rate of prematurity and therefore mortality among those with a higher birthweight ratio (Moore et al. 1990). Their perinatal management should be greatly improved now that the problems can be foreseen by routine ultrasonic examination. Various methods, including embolisation and laser coagulation, have been used to cause feticide of the acardiac twin (Ch. 9).

Death of one fetus

The possible dangers of an intrauterine death to a surviving monochorionic twin are now well recognised. Many types of anomaly have been reported in the surviving twin (Little and Bryan 1988) and the nature of these anomalies probably depends on the stage of gestation at which the co-twin dies (Hoyme et al. 1981). Review of pooled data on 53 cases suggests that disruptions of the central nervous system are the most common complication (72%), followed by the gastrointestinal system (19%), kidneys (15%) and lungs (8%) (Szymonowicz et al. 1986). Cardiac malformations have also been reported (Corney et al. 1983), as have cases of aplasia cutis (Mannino et al. 1977). These diverse lesions are probably all the result of a damaging, if not lethal, hypoxic episode resulting from the severe transient hypotension that may occur as the vascular resistance falls in the dying fetus (Fusi et al. 1991). A systematic review reported the risks following death of a co-twin. For dichorionic twin pregnancies, there was a 57% risk of preterm birth, a 1% risk of neurological abnormality and a 4% risk of death. The equivalent risks for monochorionic twin pregnancies were 68%, 18% and 12% (Ong et al. 2006).

Intrapartum management

In view of the increased risks of intrauterine death, many obstetricians recommend earlier elective delivery of twins. Given the effects of chorionicity, this is also used in informing the time of delivery. Many units will deliver MCDA twins at 36 weeks and DCDA twins at 38 weeks. However, this approach is probably associated with an increased risk of respiratory complications, such as transient tachypnoea of the newborn.

Conventional practice has been to aim for vaginal delivery where the first twin is in a cephalic presentation. More recently, there has been a trend for elective caesarean delivery for MCDA twins in view of the risk of acute intrapartum TTTS. Vaginal delivery of the second twin has for some time been recognised as a time of particular risk. Following delivery of the first twin, there is a risk of cord prolapse, abruption and malpresentation. Studies of nationally collected data from the UK have demonstrated increased rates of perinatal death of the second twin at term (Smith et al. 2005). A multicentre randomised controlled trial of elective caesarean versus attempting vaginal birth is currently in progress and should provide clear evidence for or against the routine use of caesarean delivery. When vaginal birth is attempted, this is usually done with continuous electronic fetal monitoring. Epidural anaesthesia is recommended as it facilitates manipulations to deliver the second twin, such as internal podalic version and breech extraction.

Postnatal management: routine

Examination of the newborn should focus on risks identified: congenital anomalies, deformities from intrauterine crowding, dislocated hips, cardiac examination. It is helpful to examine twins side by side when assessing discordance (Samanich 2009).

It is enormously important for a mother of twins to establish the easiest and most satisfactory feeding routine for both herself and her babies as soon as possible (Leonard 2003). For far too many, the feeding of twins is remembered as a period of frustration, exhaustion and failure. Many who planned to breastfeed have been bitterly disappointed.

For some, the advantages of bottle feeding so that others can feed their babies outweigh other considerations. But any mother who would like to breastfeed should be given every encouragement and

practical help. Most mothers can fully breastfeed two babies but they will need informed prenatal preparation (Flidel-Rimon and Shinwell 2002; Leonard 2003), including demonstrations by mothers, as well as a lot of help during the neonatal period. No mother should be expected to feed her newborn twins simultaneously without an attendant.

Whether the babies are fed together or separately is entirely up to the mother's preference and practicality. There have been no studies that compare milk production in the two methods. Many find it easier to feed separately initially until breastfeeding is well established.

Co-bedding

Many parents now choose to co-bed their twins in the neonatal period and early months. Preliminary studies suggest that the babies may have more settled sleep and more synchronous waking (Nyqvist and Lutes 1998). In preterm twins, more rapid weight gain and earlier discharge from hospital have been reported (Corney et al. 1972). A recent study found that there was no significant increase in core temperature or lowering of oxygen saturation in co-bedded infants (Ball et al. personal communication). There is currently no evidence of an increase in sudden infant death syndrome in co-bedded twins and there is anecdotal evidence that such physical contact with each other can reduce the frequency of apnoeic episodes in some preterm pairs. Furthermore, babies in one cot have the advantage of being more likely to remain longer in the parents' bedroom.

Postnatal management: high-risk care

The risks identified for both monochorionic and dichorionic twins should determine our planning of postnatal assessment and clinical care. TTTS is a major cause of morbidity, mortality and preterm delivery. Growth discordance >20% increases early perinatal morbidity and mortality when associated with fetal growth restriction and/or low birth weight (Alam et al. 2009). Acute and long-term assessment of cardiac structure and function, renal function, neurological damage and outcome, necrotising enterocolitis, growth and genetic risks should be part of routine postnatal assessment and planning. If there is risk of TTTS, early identification of birthweight, haemoglobin and bilirubin helps identify the donor and recipient twin. Early assessment of cardiac structure and function should be considered for both twins, including blood pressure assessment. Renal function and fluid management require careful consideration for both the recipient and donor twin in conjunction with the results of cardiac and blood pressure assessments. Enteral feeding should be planned to minimise the risk of necrotising enterocolitis. Cranial ultrasound and magnetic resonance imaging can help identify the development of periventricular leukomalacia. Long-term outpatient follow-up should in particular consider neurodevelopment assessment as well as cardiac and blood pressure assessment.

Bereavement

Parents who lose one twin face particular problems (Lewis and Bryan 1988; Bryan 1995). They have to experience the joy of a new baby and the tragedy of bereavement simultaneously. Because they still have a live infant their loss is usually greatly underestimated.

The parents are too often discouraged from talking about their dead baby. Yet concentration on the healthy baby to the exclusion of the stillbirth or neonatal death may encourage the mother to idealise the dead child (her angel baby) and hence alienate her from the survivor, especially if the surviving twin is difficult to handle because of illness or disturbed behaviour.

The pride involved in expecting twins is enormous, and failure is therefore deeply felt. Mothers inevitably feel shame and often some guilt. This guilt may be increased by any implication from friends or medical staff that the death was all for the best, even if logically this may seem so. Twinship is also important to the survivor and this continues into adulthood. This has implications for the care of the surviving twin and parents from birth onwards (Woodward 1998).

Some parents have difficulty in distinguishing the two babies in their own minds. Some may feel that the dead one never existed – a fantasy baby. Substantive mementos, such as photographs or even an ultrasound scan showing the two babies together, can help to clear the emotional confusion. Naming the dead baby not only helps to distinguish the babies but later makes it much easier to talk to the survivor (who should always be told) about the twin.

Blood or placental samples should always be taken for zygosity determination. Even if one baby dies, parents usually want to know whether or not their twins were identical. The zygosity may also be important for reliable genetic counselling about congenital anomalies and the chances of further twin conceptions.

Where both babies are born alive but one baby is likely to die, the family should be encouraged to spend extra time with this one so that precious memories can be created and the parents may later find comfort in knowing that they gave this baby as much love and care as they could. A photograph of the two babies (together with their parents if they so wish) should be taken as quickly as possible.

If a twin is born dead before 24 completed weeks of the pregnancy (a miscarriage) and a sibling is liveborn, the legal paradox and ambiguity add to the parents' difficulties.

Most, if not all, mothers continue to think of their surviving child as a twin even if the other baby was stillborn. Many parents welcome the opportunity to reminisce about their lost baby, particularly with the medical staff, who may be the only people who knew the baby. Many years later they still appreciate an enquiry about their feelings towards the dead baby and any concerns about the survivor's feelings about the dead twin.

An increasing number of parents are likely to face bereavement by choosing to lose a malformed twin fetus through selective feticide. Their grief can be powerful but may be delayed until the delivery of the healthy baby. It is important that the fetus is respected and its loss recognised (Bryan 2004).

Parents' responses to the loss of normal fetuses in a multifetal pregnancy reduction vary (Bryan 2002). Some are just relieved to

have two (or one) healthy babies. Others will value support in coping with their guilt and grief over the death of one or more potentially healthy children. Some will not wish the subject to be mentioned, especially if they have not told their family.

Social

Parents of multiples need particular understanding. Few are prepared for the emotional as well as practical and financial stresses involved in caring for more than one baby at once (Taylor and Emery 1988; Botting et al. 1990; Spillman 1992; Garel et al. 1997). They are often faced not only with the problem of caring for and relating to two babies at once but also with two babies, each of whom is more difficult because of the prematurity, low birthweight and other neonatal problems already described.

A mother's relationship with her babies will be further impeded if she finds it difficult to tell them apart. The babies should always be clearly identifiable and called by their names. The cot should be made recognisable at a distance so that the parents can start relating to the particular baby as they approach. Similarly, parents should be encouraged to dress the babies differently from the start despite pressure from friends and relatives. Twin names such as Joy and Jay or Robert and Roberta are also best avoided if the children's individuality is to be respected.

The long-term effects of early mother–twin relationships have yet to be established. Mothers of preterm twins have been found to show fewer initiatives and responses to their babies than mothers of preterm singletons and to be less responsive to both positive signals and to crying. They also had less physical contact with, and talked less to, them. At 18 months, the cognitive development of the twins was less advanced than that of the single-born controls and maternal behaviour in the newborn period was predictive of the level of development of the children at 18 months (Ostfeld et al. 2000).

One twin may be ready to go home before the other, but most units now try to discharge the babies together; otherwise, the baby left behind may suffer in his or her relationship with the mother. Moreover, it has been shown that earlier discharge from hospital is the most important factor affecting the self-esteem of a school-age twin (Hay and O'Brien 1987). If discharge together is not practicable, because one baby needs a much longer stay, parents should be encouraged and helped to visit the remaining baby. Facilities for the healthy child to attend with the parents must always be provided.

Introduction

Medicines have made a significant contribution to reducing both mortality and morbidity in neonates. The benefits of antibiotics, analgesics, surfactant and anticonvulsants are discussed in detail in other sections of this textbook.

The practising neonatologist does not need to be an expert in clinical pharmacology. There are, however, advantages in understanding basic facts regarding how neonates handle medicines and

the practical problems associated with the administration of medicines to neonates of different weights and gestation.

History of drug toxicity in neonates

Some of the most important examples of drug toxicity in humans have occurred in newborn infants or the developing fetus. These cases illustrate the difference between neonates and adults in relation to drug absorption, distribution, metabolism and toxicity, as well as formulation issues (Table 24.1).

Percutaneous toxicity

One of the earliest recognised drug toxicities in humans was methaemoglobinaemia, due to the effects of aniline dye, which was reported in 1886. The dye had been used to stamp the name of the institution on nappies for newborn babies. Ten newborn infants developed cyanosis after percutaneous absorption of the dye. Several months later another outbreak was observed and the connection to the dye was noted (Choonara and Rieder 2002). Subsequently there have been other cases of newborn infants developing cyanosis following percutaneous absorption of aniline dye.

The absorption of compounds is enhanced by prolonged contact of a wet nappy with the perineum. The greater surface area to weight ratio of newborn infants in comparison with children and adults results in greater relative exposure of topical medicines/chemicals. Also the relative increase in the water content of the dermis and the thinner stratum corneum facilitate transcutaneous diffusion of small molecules. There have been other examples of percutaneous toxicity occurring in the newborn infant, including neurotoxicity in association with hexachlorophane and hypothyroidism following the use of topical iodine (Choonara and Rieder 2002).

Protein binding and sulphonamides

In 1956, Silverman and colleagues reported a difference in mortality rate and kernicterus among premature infants who received two different antibiotic regimens (Choonara and Rieder 2002). Neonates who received a combination of penicillin and sulphisoxazole had a significantly higher mortality than those who received oxytetracycline. It was almost 10 years before laboratory studies showed that the sulphonamide had displaced bilirubin from albumin by nature

of its higher binding affinity. This marked increase in the free bilirubin concentration resulted in kernicterus. This unfortunate adverse drug reaction shows the importance of considering protein binding of drugs in the neonate. This is especially so in sick preterm infants where there are high plasma concentrations of bilirubin together with an impaired capacity to metabolise and excrete bilirubin due to the reduced activity of glucuronosyltransferase.

Impaired metabolism and chloramphenicol

In 1959, the grey-baby syndrome was reported with the antibiotic chloramphenicol. Newborn infants developed abdominal distension, vomiting, cyanosis, cardiovascular collapse, irregular respiration and eventually death (Choonara and Rieder 2002). The following year, pharmacokinetic studies showed that neonates were unable to metabolise chloramphenicol to the same extent as children and adults. This was due to impaired glucuronidation of chloramphenicol, and a halving of the dose of chloramphenicol prevented the development of the grey-baby syndrome. Recognition of the limited capacity for drug metabolism in the neonate has led to more appropriate dosage regimens for other medicines.

Thalidomide and teratogenicity

Only 2 years after the death of several newborn infants in association with the use of chloramphenicol, a short letter to *The Lancet* reported the possible association between the administration of thalidomide, given as an antiemetic or sedative during pregnancy, and multiple congenital abnormalities in the newborn infant, in particular phocomelia (McBride 1961). Thalidomide was an exceptionally safe antiemetic when studied in healthy adult volunteers. Animal studies involving thalidomide in pregnant rats initially showed no evidence of teratogenicity. Careful retrospective analysis showed that the effect of thalidomide on the human fetus was time-specific (Table 24.2). Subsequent studies in rats showed that the species was sensitive but only at 12 days' gestation. It is important to remember the difference between the human fetus and animal models and to be aware of the potential teratogenic effect of medicines that are otherwise exceptionally safe.

Thalidomide itself is not teratogenic. It is the metabolites of thalidomide, in particular the monocarboxylic and dicarboxylic metabolites, that are teratogenic. These metabolites, however, do not cross over from maternal plasma into the fetus. Thalidomide

Table 24.1 Important examples of drug toxicity in the neonate

YEAR	DRUG/COMPOUND	TOXICITY	MECHANISM
1886	Aniline dye	Methaemoglobinaemia	Percutaneous absorption
1956	Sulphisoxazole	Kernicterus	Bilirubin displacement from plasma proteins
1959	Chloramphenicol	Grey-baby syndrome	Impaired metabolism
1961	Thalidomide	Phocomelia	Fetal production of teratogenic metabolite
1982	Sodium chloride/water	Alcohol poisoning	Formulation
1984	Vitamin E and renal failure	Coagulopathy, hepatic	Formulation?
1998	Cisapride	Arrhythmia	Drug interaction
2006	Ceftriaxone	Calcium precipitation in heart and lungs	Drug interaction

Table 24.2 Time course of thalidomide teratogenicity in humans

DAYS' GESTATION ON EXPOSURE	EFFECT
21–22	Absence of external ears and paralysis of central nerves
24–27	Phocomelia of arms
26–29	Phocomelia of legs
34–36	Hypoplastic thumbs and anorectal stenosis

itself crosses over into the fetus and is then metabolised to produce the toxic metabolites. It is unfortunate that the fetus with limited capacity to metabolise medicines can, in this case, metabolise the drug with the subsequent formation of a potent teratogen.

Formulation problems

In the early 1980s there were two major tragedies involving premature infants that were thought to be related to the constituents of the medicinal products rather than the drug itself. Ten ventilated preterm infants developed central nervous system depression with associated hypotonia, apnoea and seizures (Gershnik *et al.* 1982). This was followed by a severe metabolic acidosis and multiorgan failure and was described as the gasping syndrome. These infants all had umbilical arterial catheters and were receiving multiple injections of heparinised bacteriostatic sodium chloride, used for flushing the catheters, and also medications reconstituted with bacteriostatic water. Both the sodium chloride and the water contained 0.9% benzylalcohol. The infants who died had significant levels of benzylalcohol in their serum.

The unit that described this inadvertent poisoning stopped using bacteriostatic saline and water and subsequently no further cases were noted. The healthy adult can tolerate up to 30 ml of 0.9% benzylalcohol as a single dose (approximately 0.5 ml/kg). The newborn infants who developed the gasping syndrome were receiving between 20 and 50 times this amount on a daily basis.

In 1983, an intravenous (IV) form of vitamin E was marketed as a prevention for the retinopathy of prematurity. Seven months later, E-ferol was withdrawn from the market following the deaths of 38 infants who had received the drug (Phelps 1984). The affected infants showed signs of hepatic, renal and haematopoietic toxicity. It has been postulated that the emulsifiers used to solubilise vitamin E were responsible.

Ceftriaxone and calcium drug interaction

Ceftriaxone is a widely used cephalosporin. It is a highly protein-bound antibiotic and may displace bilirubin. Despite these concerns it has, however, been extensively used in neonates. In 2002 a fatality was reported following co-administration of ceftriaxone and calcium-containing solutions to a neonate in France. This report resulted in a national pharmacovigilance investigation and in 2006 the French Health Products Safety Agency issued a warning letter regarding the risk of precipitation of ceftriaxone–calcium salt in neonates. There have been seven reported deaths worldwide (Bradley *et al.* 2009). Ceftriaxone is therefore no

longer recommended in the neonatal period (World Health Organization 2008).

Licensing

The Medicines Act of 1968 requires that all medicines manufactured or marketed in the UK have been authorised and examined for efficacy, safety and quality. The Medicines Act was introduced in response to significant cases of drug toxicity that occurred in the late 1950s and early 1960s. Two of these involved the developing fetus (thalidomide) and the newborn infant (chloramphenicol). It is ironic that legislation that was introduced to protect all humans has failed to protect those who are at the greatest risk – newborn infants. This is despite the fact that tragedies in the newborn infant precipitated the legislation.

Unlicensed and off-label use

Unlicensed medicines involve modifications to a licensed medicine (e.g. tablets that are crushed and prepared into suspensions), using chemicals as medicines, the manufacture of formulations under a 'specials' licence and using medicines licensed in other countries. A particular problem in neonates and children is the off-label use of medicines. This includes the use of licensed medicines: at doses outside that stated in the product licence; for different indications; outside the licensed age range; and by an alternative route, e.g. the use of an IV formulation orally.

Over 50% of drug prescriptions on a British neonatal intensive care unit were off-label and 90% of babies received a drug that was either unlicensed or used in an off-label way (Conroy *et al.* 1999). Such results do not imply that current prescribing is inappropriate but reflect the lack of scientific evidence and appropriate formulations for drug therapy in the neonate. In children there is a greater risk associated with the use of unlicensed and off-label medicines (Turner *et al.* 1999). This is not to say that clinicians should restrict themselves to the use of licensed products. However, neonates deserve the same high standards in drug treatment as adults. This can only be achieved by the scientific study of clinically needed medicines in newborn infants in a controlled setting. Such clinical trials would not only provide evidence of efficacy but also reduce the number of deaths associated with the use of new medicines in a non-controlled manner. If there are deaths in a clinical trial, the investigators and regulatory authorities have a responsibility to review the reasons for any deaths at an early stage and to consider whether the experimental drug may be responsible. A review of published paediatric clinical trials over a 7 year period identified 99 randomised controlled clinical trials in neonates (Sammons *et al.* 2008). Three of the trials involving neonates were then terminated prematurely by independent safety monitoring committees because of drug toxicity. In nine other neonatal clinical trials, patients experienced severe drug toxicity.

Furthermore, licensing should provide appropriate formulations. Many ampoules of off-label drugs contain amounts such that 10-fold errors can occur with the use of a single vial, e.g. morphine.

Legislative changes

In Europe and the USA, new legislation has been introduced that provides a financial incentive for the pharmaceutical industry to study appropriate medicines in newborn infants. It is essential that any clinical trials in neonates involve medicines that are likely to be of significant clinical benefit to neonates and are not simply

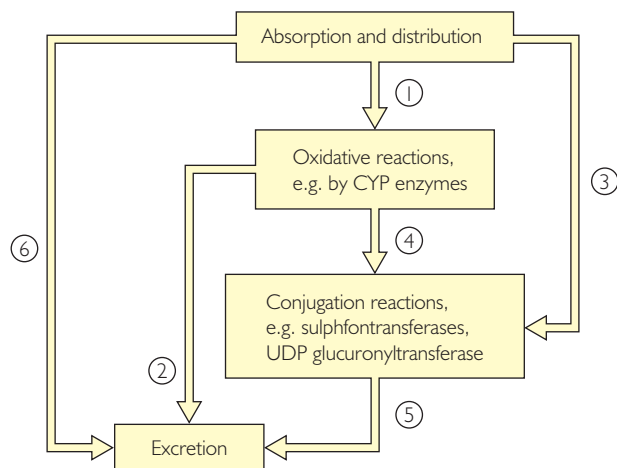

Fig. 24.1 Biotransformation of drugs. 1, Transformation of hydrophobic compounds to more soluble compounds by adding a functional group (oxygen, sulphur or carbon). (Adapted from *de Wildt et al. (1999a).*)

studied to increase the considerable profits that can be obtained by such a patent extension.

Drug handling

Large variations in gestation, size and disease states, combined with rapid maturational changes, make optimising drug therapy in the neonatal period more challenging than at any other time. This section focuses on what the body might do to drugs, using specific examples relevant to clinical practice to illustrate key principles. An overview of the major components involved in drug handling is given in [Figure 24.1](#).

Absorption

Many drugs in neonatal practice are administered IV and bypass the need for absorption. All the drug delivered can be assumed to be available to the body. However, for drugs administered extravascularly, the body compartment to which the drug is delivered is usually separated from the intended site of action and absorption is an important first step in making the drug available. The fraction of drugs absorbed by a given route compared with an IV dose is called the bioavailability. Absorption characteristics are relevant to drugs given orally, intramuscularly, rectally or transcutaneously. In practice, oral administration is the only one commonly used, as the variability from the other sites is usually too great for predictable drug therapy.

Clinical implications

Absorption from the gastrointestinal tract will depend on the physicochemical properties of the drug and individual patient factors and may be significantly different in newborns ([Box 24.1](#)).

In the immediate newborn period, gastric pH may be neutral. With increasing maturity and postnatal age, there is a decrease in intragastric pH ([Kelly et al. 1993](#)). There is a rapid fall within hours

Box 24.1 Factors affecting drug absorption

Drug properties

Gastrointestinal microflora
Enzyme activity in gut wall
Gastrointestinal blood flow

to between 1.5 and 3.5 in preterm and term infants. However, other factors such as feeds make it difficult to maintain an acid pH consistently in the neonatal period. Acid-labile drugs, such as oral penicillin, may have enhanced absorption. Acidic drugs, such as phenobarbital, may have reduced absorption, owing to their increased degree of ionisation in the more neutral environment.

The gastric emptying time will affect the absorption time profile. Gut motility is influenced by gestational age, postnatal age and the type of feeding used ([Riezzo et al. 2001](#)). Another variable that alters absorption is the colonisation of the gastrointestinal tract with microflora. This is influenced by maternal flora, type of feed and antibiotic use. The metabolic capacity of microflora may influence absorption of drugs, but the clinical importance of this is far from clear.

Nevertheless, some drugs are given orally with good effect. Caffeine to treat apnoea of prematurity is often administered by an oral route, and effective, therapeutic concentrations of caffeine are achieved rapidly ([Giacoia et al. 1989](#)).

Key message

Absorption of drugs given by the extravascular route will depend on the physicochemical properties of the drug and patient characteristics. Extreme variability in patient characteristics means that extrapolating bioavailability data from adult studies is flawed. Furthermore, other issues such as administration difficulties, losses due to vomiting and spillage may be far more important determinants of drug effect than absorption characteristics. Oral administration cannot guarantee predictable drug delivery in the critical situation.

Drug distribution

In an optimum drug dosage regimen, a desired target concentration is achieved. This requires consideration of the distribution volume of the drug, usually referred to as the apparent volume of distribution (V_d). This is not a real physiological volume but relates the amount of drug in the body to the blood concentration. Distribution of the drug depends on:

- the size of the body water and fat compartments
- protein-binding capacity
- haemodynamic factors such as cardiac output and regional blood flow.

Clinical implications

The age-related changes in body compartments and protein binding are particularly relevant in the neonatal period. In adults, total body water is 50–55% of bodyweight. In an extremely premature infant, total body water constitutes approximately 92% of bodyweight and body fat less than 1%. At term, total body water is around 75% of bodyweight and body fat has increased to 15%. The intracellular volume increases from 25% bodyweight in the preterm infant to around 33% at term. Selecting a drug dose is made more difficult by rapid postnatal changes. There is a rapid contraction in the extracellular volume shortly after birth, with interstitial fluid loss (Hartnoll et al. 2000).

For water-soluble drugs, the differences in body composition tend to result in a V_d that is greater in newborns, especially preterms. Therefore, at equal doses per bodyweight, peak concentrations in blood will be lower (although mean concentration at steady state is unaffected by V_d). For drugs distributed mainly in the extracellular fluid space, the dose required on a milligram per kilogram basis would be significantly greater, because of the larger extracellular fluid compartment. However, for highly lipophilic drugs, very premature infants may have a reduced V_d .

Aminoglycosides, such as gentamicin, bind minimally to proteins and are mainly distributed in body water. Therefore, in preterm infants, the V_d is greater (0.35–0.75 l/kg) (Vervelde et al. 1999; Rocha et al. 2000) and a higher loading dose is required.

By contrast, benzodiazepines are lipophilic and highly protein-bound. The median V_d of midazolam in preterm neonates is 1.1 l/kg, which is similar to that seen in children or adults (de Wildt et al. 2001). Recommended loading doses per bodyweight are similar in neonates and children.

Protein binding

The pharmacological effect of a drug is related to the unbound fraction in the blood. The degree of binding to plasma proteins is a major factor in determining drug distribution. The age-related quantitative and qualitative changes in plasma proteins are crucial to the likely clinical effects. Acidic and neutral drugs are largely bound to albumin, whereas basic drugs bind to albumin, α_1 -acid glycoprotein and lipoprotein.

Clinical implications

With increasing prematurity, the total plasma protein and plasma albumin are lower (Pacifi et al. 1986) and the binding affinity less. The consequence is increased concentrations of unbound drug. Protein binding is also affected by endogenous substances, most notably bilirubin. Because of competitive binding, increased bilirubin levels may displace and therefore increase the free drug levels. Conversely, certain drugs may displace bilirubin from albumin-binding sites and so increase the risk of bilirubin toxicity. In practice, it is only when plasma protein binding is high (90% or more) that clinically important displacement of bilirubin will occur. Table 24.3 shows examples of where this may happen.

The in vitro binding studies alert us to potential risks of drugs displacing bilirubin. The affinity for albumin binding by bilirubin exceeds the affinity for most drugs and the clinical risk is likely to be very small. Clinical problems are likely to occur with drugs such as indometacin, other non-steroidal anti-inflammatory drugs, ceftriaxone and X-ray contrast media.

Table 24.3 Protein binding of drugs

DRUG	% BOUND TO PROTEIN	POTENTIAL PROBLEM
Aspirin	95	Yes
Caffeine	25	No
Ceftriaxone	83–96	Yes
Diazepam	75–90	Possible
Digoxin	16–30	No
Furosemide	95	Yes
Indometacin	95	Yes
Penicillin	65	No
Phenobarbital	20–35	No
Phenytoin	90	Yes
Theophylline	35–55	No

Key message

The neonate has a very different body composition and protein-binding capacity. Rapid changes occur in the context of a unique set of circumstances for each individual, altering the V_d and protein binding. Predicting drug levels, both blood and tissue, is difficult, and standard pharmacokinetic data from adults are of little practical help.

Biotransformation

The process of removing the drug from the body is called clearance, and the total body clearance is a summation of all the clearance mechanisms involved. There are a number of pathways that can lead to the elimination of drugs from the body (see Fig. 24.1) but the two principal mechanisms in the newborn are the hepatic and renal pathways. The ontogeny of these clearance mechanisms is crucial to the pharmacological response of the newborn (Alcorn and McNamara 2002; Bartelink et al. 2006; Anderson and Lynn 2009).

For many drugs, elimination requires a chemical alteration of the drug molecule: biotransformation. Most drugs are lipophilic and transformation to more water-soluble metabolites is a key step. Biotransformation reactions are conventionally grouped into two main types, phase 1 and phase 2 reactions. Phase 1 reactions, by adding or revealing a functional group (oxygen, sulphur or carbon), make a compound more water-soluble. This may then be directly excreted or act as a substrate for the phase 2 reaction.

The primary organ for drug biotransformation is the liver, where a variety of enzymes are involved in modifying both endogenous and exogenous substances. Other organs such as the kidney, gut, lung and skin may also have some biotransforming capacity. These are probably of little clinical relevance.

Phase 1 reactions

Phase 1 reactions include oxidation, reduction, hydrolysis and hydroxylation reactions. Most of these are carried out by the hepatic cytochrome P-450 (CYP) oxidase system, involving haem-containing

Table 24.4 Major cytochromes involved in drug metabolism

CYP	ACTIVITY IN NEONATES	DRUG SUBSTRATES OF THE ENZYME	DRUG INHIBITORS OF THE ENZYME
1A2	↓	Caffeine Theophylline	Amiodarone Cimetidine
2C9	↓	Ibuprofen Phenytoin	Amiodarone Fluconazole
2C19	↓	Diazepam	Cimetidine Indometacin
2D6	↓?	Codeine Metoclopramide	Amiodarone Cimetidine Ranitidine
2E1	↓	Paracetamol	
3A4/7	↓ (3A4) ↑ (3A7)	Cisapride Erythromycin Fentanyl Lidocaine Midazolam	Amiodarone Cimetidine Ciprofloxacin Erythromycin Fluconazole
CYP, cytochrome P-450.			

proteins. The nomenclature for CYP uses a three-tier classification based on the genes: the family (at least 40% homology, e.g. CYP3), a subfamily (highly related genes, e.g. CYP3A) and the individual gene (e.g. CYP3A4). The isoforms of the 3A subfamily (CYP3A4, CYP3A5, CYP3A7) account for the majority of drug-metabolising enzymes. They are responsible for the metabolism of about 50% of drugs (Alcorn and McNamara 2002). The activity of most enzymes is significantly reduced in the neonate (Table 24.4). The neonate compensates for reduced activity in the major pathways by utilising alternative pathways. Enzyme activity may increase rapidly after birth (CYP2D and CYP2E1) or slowly during infancy (CYP1A2).

Phase 2 reactions

In these reactions, excretion of the drug is enhanced by conjugation of endogenous molecules to drug substrate. The important reactions in the newborn are glucuronidation, sulphation, acetylation, glutathione conjugation, methylation and amino acid conjugation. Compared with phase 1 enzymes, the ontogeny of these phase 2 reactions is less well established.

Clinical implications

The rapidly changing balance of different enzymes explains many of the noticeable differences in drug clearance during the newborn period. Each enzyme has an independent developmental pattern. Fetal CYP enzymes such as CYP3A7 decline rapidly after birth and activities of neonatal ones such as CYP3A4 rise within a few weeks of birth and continue to do so in the first year (de Wildt et al. 1999a). Such changes have been used to generate models to predict clearance of drugs but such models still lack accuracy (Björkman 2006).

Glucuronidation is most deficient in the immediate neonatal period, and other conjugation pathways, such as sulphation, have to compensate. Methylation reactions are often insignificant in adults but may have a prominent role in the neonate. However, as a review of the glucuronosyl transferase (UGT) isoforms indicated,

clinically useful generalisations are hard to make (de Wildt et al. 1999b). In practice, there is large interindividual variability to glucuronidation activity. The various disease states and environmental factors, as well as changes in UGT, contribute to this (Allegaert et al. 2009).

Examples

Midazolam clearance reflects hepatic CYP3A, and, in adults, clearance correlates with hepatic CYP3A4/5 activity. Plasma clearance is reduced in the newborn period, particularly in the preterm infant (Jacqz-Aigrain et al. 1990).

Theophylline is a CYP1A2 substrate. Clearance is low in the first few days after birth. CYP1A2 activity increases over the first 6 months of life. The clearance and metabolite pattern reaches adult values by 55 weeks of age and is mainly related to post-conceptual age.

Propofol clearance involves both phase 1 (hydroxylation, mainly CYP2B6) and phase 2 (glucuronidation) reactions. Clearance in preterm and term neonates is reduced and shows significant inter-individual variation (Allegaert et al. 2007). Propofol may be useful in neonates but should be used cautiously because of the risks of accumulation and the large interindividual variability (Allegaert et al. 2007).

Paracetamol is metabolised by glucuronidation and sulphation. These combined account for 82% and 68% of paracetamol metabolites excreted in the urine in adults and children, respectively. There are significant changes in the elimination pathway with increasing maturity. The sulphation pathway is relatively well developed compared with glucuronidation in the fetal/early neonatal period, as demonstrated by a low glucuronide to sulphate ratio in the preterm infant (0.1–0.2) (van Lingen et al. 1999). This changes over time to 0.3, 0.75, 1.6 and 1.8 in the term infant, young child, adolescent and adult, respectively (Levy et al. 1975; Miller et al. 1976). The clearance increases with postconceptional age and therefore dose regimens that achieve a target concentration must be adapted accordingly (Table 24.5) (Anderson et al. 2002).

Table 24.5 Clearance and dose for paracetamol

POSTCONCEPTIONAL AGE (weeks)	CLEARANCE (ml/min/kg)	SUGGESTED DOSE (mg/kg/day)
30	1.33	25
34	2.33	45
40	3.50	60
60	4.50	90

Morphine is conjugated in the liver to morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G). The analgesic properties are thought to come from morphine and M6G. Glucuronidation of morphine is reduced in premature infants and morphine clearance in the neonate (range 0.8–7.8 ml/min/kg) closely correlates with increasing postconceptional age (Saarenmaa et al. 2000). As would be predicted, clearance in children (25 ml/min/kg) is considerably greater.

Key message

Biotransformation in the liver is a key step in the effective clearance of many drugs. Although understanding of the processes involved is incomplete, appreciation of those maturational factors already known can help in rational drug selection and dosing regimes.

Excretion

Most drugs or their metabolites are ultimately eliminated from the body via the kidney. Renal excretion depends on glomerular filtration, tubular reabsorption and tubular secretion. The dynamics of this system change with advancing maturity and postnatal age.

The elimination half-life ($t_{1/2}$) describes the disappearance of a drug from the blood and is the time taken for the concentration of a drug to fall by one-half. It is helpful in determining drug dose intervals. Many drugs follow first-order kinetics and are eliminated by the kidneys in proportion to the glomerular filtration rate (GFR). Knowledge of the $t_{1/2}$ for the drug will then allow dose adjustment when renal function is impaired, a common problem in the neonatal period.

Clinical implications

The amount of drug filtered by the glomerulus depends on its functional capacity and the blood flow. The amount of drug–protein binding is also a determinant, as the amount of drug filtered is inversely related to the degree of protein binding.

During fetal life, GFR is low. It rises with increasing gestational age but is constant when corrected for fetal bodyweight. At birth, the GFR in preterm infants is 0.6–0.8 ml/min and in term infants 2–4 ml/min (van den Anker 1996). Increases in cardiac output, changes in vascular resistance that increase renal blood flow and increased permeability of the glomerular membrane result in significant increases in GFR in the first few days of life. These changes occur in both term and preterm infants. The implication for many drugs in the immediate newborn period, particularly for preterm infants, is a longer $t_{1/2}$ and extended dosing interval. However, this then changes during the first week of life. Changes in serum creatinine after the first 48 hours of life may give an approximate measure of the newborn's GFR (Drukker and Guignard 2002).

Tubular reabsorption and secretory function may be functionally immature in the neonate. The rate of maturation is slower than for GFR. This is an additional modulator in renal elimination to consider for some drugs, such as penicillins, where tubular secretion is the main mechanism of excretion. Furthermore, concomitant drugs that alter renal function or maturation, such as indometacin, can also profoundly alter excretion.

Examples

Vancomycin is eliminated by glomerular filtration and therefore gestational and postnatal age would be expected to affect the pharmacokinetics. The elimination $t_{1/2}$ in neonates ranges from 3.5 to 10 hours and there is a positive correlation with serum creatinine (James et al. 1987). Dosage schedules based on bodyweight and serum creatinine have been shown to be clinically useful (Grimsley and Thomson 1999). However, neonates rarely receive vancomycin in the first week of life when renal function is most likely to be impaired and a dosing regimen based on weight alone can be effective (de Hoog et al. 2000). Furthermore, exposure to antenatal corticosteroids diminishes the gestational age-dependent difference in the renal excretion of antibiotics.

Ceftazidime is also predominantly eliminated through glomerular filtration. With increasing gestational age and GFR, clearance increases and $t_{1/2}$ decreases; dosage recommendations should be based on gestational age and GFR.

Key message

Renal function is crucial to clearance of a drug from the serum and elimination from the body. Gestational age and postnatal age are important determinants of renal function. Dosing schedules that allow for this are required, to achieve a therapeutic drug concentration.

Drug prescribing and administration

Safe and accurate drug prescribing and administration in the neonatal patient can present complex challenges. Some of the risks involved can be minimised by applying common sense to prescribing practice. For example, there is no point in prescribing doses based on bodyweight such that it is impractical to measure the dose safely and accurately from the drug formulations available. Additionally, this may increase the risk of medication errors. It is difficult to measure volumes less than 0.05 ml accurately even with a 1-ml syringe. This applies to both IV and oral drug therapy.

Prescribing protocols should be agreed by medical, pharmacy and nursing staff which include rounding up or down doses to an

acceptable number of whole numbers or decimal places, depending on the drug and the preparations available for administration.

Oral or nasogastric route of administration

Liquid or powder formulations of medicines are necessary for oral or nasogastric administration. They should not be mixed with large volumes of milk or other feeds as interactions can occur with the feed. If the feed is not completed an inadequate dose will be administered.

Medicines contain excipients to enhance the flavour and acceptability of the formulation, or to improve solubility of the drug or to stabilise or preserve the final product. Excipients do not contribute to the pharmacological activity of the drug but may cause toxicity, e.g. phenobarbital elixir containing 38% alcohol (Whittaker et al. 2009).

Liquid medicines should always be measured in an oral syringe or suitable dropper device in order to ensure accurate measurement. Hypodermic syringes should never be used for oral or nasogastric administration as they may result in inadvertent IV administration (Cousins and Upton 1998). Many liquid medicines can be administered down a nasogastric tube when necessary, provided that adequate care is taken to prevent blockage of the tube. All doses should be flushed through using sterile water. The National Patient Safety Agency makes clear recommendations on the choice and use of equipment to ensure safe administration of liquid medicines through nasogastric and gastrostomy tubes.

Delivery of oral liquid medicines via a dropper device may be useful in babies. Accuracy of dosing depends on factors such as the angle at which the dropper is held and the viscosity and density of the product, so may not be accurate.

Topical administration

The skin of a neonate, especially if premature, offers an immature protective barrier to substances applied topically, particularly in the first week of life. The skin is well hydrated due to the high total body and extracellular fluid content in a newborn baby, and offers a large surface area for absorption in proportion to bodyweight. This has resulted in instances of drug toxicity (see above). This route of drug delivery may overcome the problems of oral or IV therapy but further work is necessary to develop reliable drug delivery systems.

Intravenous administration (Box 24.2)

Many drugs need to be diluted before they can be given intravenously in neonates. Products containing benzyl alcohol or high levels of propylene glycol should not be used in neonates because of the risk of toxicity.

Injections presented as dry powders in vials for reconstitution are likely to have a displacement volume, which must be taken into account if the correct dose is to be drawn from the vial. Caution must be exercised when drawing up the neonatal dose from proportions of vials or ampoules designed for older children or adults, in order to prevent 10-fold errors (Chappell and Newman 2004).

The hub of a syringe contains a 'dead space' that may be more than 0.1 ml (Koren 1997). Because of this, care must be taken in drawing up drugs requiring dilution. If the active drug is drawn up first, followed by the diluent, the syringe will contain around 0.1 ml extra of the concentrated drug solution. This may be clinically significant. It is therefore safer to draw up some of the diluent first into the syringe, add the required amount of drug solution from

Box 24.2 Administration of intravenous drugs

Administer the drug at an access point close to the patient
Be aware of the fluid volume and/or electrolytes administered with the drug and flush solutions
Give slowly over 3–5 minutes or as an infusion
Be aware of the danger of bolus and flushes into infusions containing maintenance drugs
Ensure that drugs and fluids are compatible before allowing them to mix together
Use a central line where possible, especially for irritant drugs, inotropes and if drugs will be required for a long time

another syringe and follow with the rest of the diluent to the required final volume.

If drugs are being given as a bolus into an IV infusion line, then they should be given at an access point as close to the patient as possible. If the infusion is running, then it is not normally necessary to flush the drug. In fluid-restricted babies, these flush volumes should be taken into account. Many drugs contain considerable amounts of sodium or potassium, e.g. benzylpenicillin injection contains 1.68 mmol sodium per 600 mg vial. This needs to be considered in babies undergoing strict fluid balance and electrolyte monitoring, or babies with unexplained electrolyte disturbances.

With drugs required to reach the patient quickly, a flush will be needed to deliver the drug to the patient in the required timeframe. Similarly, with drugs undergoing monitoring, such as aminoglycoside antibiotics, it is important that the time the drug is delivered to the patient is known for results to be interpretable; hence a flush is advisable.

Entry sites should be carefully observed for signs of thrombophlebitis or 'tissuing'. They should not be bandaged in a manner that obscures a good view of the tissues surrounding the point of cannula entry. Peripheral veins with comparatively slow blood flow will be irritated by a high osmotic load, extremes of pH and some chemical substances and excipients. Central venous access should be used for irritant or inotropic drugs, and for administration of medicines over long periods of time. Preterm infants are particularly vulnerable to extravasation and tissue damage because of the fragility of their vascular system and skin.

In-line filters (0.22 µm) have been suggested to be effective in removing air, particulate matter, microbial contaminants and endotoxins. Some of the available products are appropriate for neonatal use as they are of low volume and therefore do not require large flush volumes to push drugs through them. There is insufficient evidence to recommend the use of IV in-line filters to prevent morbidity or mortality in neonates (Foster et al. 2006). However, intravenous administration sets and lines only required changing every 4 days when a 0.2-µm filter removing endotoxins was used, therefore saving time and money without an increase in adverse outcomes.

Intramuscular administration

The intramuscular (IM) route of administration should be avoided if possible, as it is a painful route of administration, especially in the neonate who has very little muscle mass. It is also an unreliable route of drug administration, as absorption from the IM site can be slow and erratic. This is due to poor blood supply to the site, reduced muscular contractions and vasomotor instability, which can result in an exaggerated vasoconstriction reflex, further reducing

blood flow to the site (Barrett and Rutter 1994). The IM route should never be used if there is a bleeding problem, e.g. thrombocytopenia or in a patient on anticoagulants.

Rectal administration

This can be a useful route of administration for some drugs if the oral and IV routes are not available, though, in the neonate, absorption may be less complete and slower than if drugs are given orally or IV. Suppositories containing appropriate neonatal doses, however, are not always available. Suppositories are often cut in half or quarters. The drug content is not necessarily distributed evenly through the suppository and therefore the actual dose administered may differ from that intended. Consequently, this is a practice that should not be encouraged.

Drug interactions

Serious drug interactions are fortunately uncommon. They are preventable by the involvement of clinical pharmacists in reviewing drug prescription charts. Some of the major types of drug interactions and their mechanisms are described below (Table 24.6). The most important recent drug interaction in neonates has been the formation and precipitation of ceftriaxone–calcium salts in neonates who have received intravenous ceftriaxone alongside solutions containing intravenous calcium (World Health Organization 2008). This drug interaction has resulted in the death of at least seven neonates (Bradley et al. 2009). As different health professionals at different time points may separately prescribe ceftriaxone and calcium-containing intravenous solutions, including parenteral nutrition, it is best to avoid the use of ceftriaxone entirely in the neonatal period.

Pharmacodynamic interactions

These occur when drugs given together have similar or antagonistic pharmacological effects or side-effects. Such interactions are usually predictable from a knowledge of the pharmacology of both drugs and may be caused by competition at receptor sites or occur when both drugs act on the same physiological system.

When morphine and midazolam are administered together to provide analgesia and sedation for ventilation, the two drugs interact. Their similar adverse effect profile causes increased sedation (in this case the desired effect) and respiratory depression. However, they can be given safely together, provided that adequate monitoring of the patient is assured, appropriate respiratory support is available and dose adjustment is performed in relation to the clinical response of the patient.

Pharmacokinetic interactions

If the administration of one drug changes the absorption, distribution, metabolism or excretion of another drug, resulting in an increased or decreased amount of drug becoming available to produce an effect, then this is a pharmacokinetic interaction. They can be divided into several types.

Drug absorption interactions

The rate of absorption of a drug, or the total amount finally absorbed, may be altered by such an interaction. Delayed absorption is unlikely to be a major clinical problem, unless the drug involved requires a high peak plasma concentration to be rapidly achieved, e.g. a sedative or an analgesic agent. However, if the interaction results in a reduction in the total amount of drug absorbed, the result may be ineffective therapy.

Protein-binding alterations

Most drugs are bound loosely to plasma proteins. Drugs can displace each other from such protein-binding sites, and the displaced drug will therefore be available for effect or toxicity in its free form in the plasma. This is only likely to be significant if the drug is normally extensively protein-bound, i.e. to an extent greater than 90%, and is not normally widely distributed throughout the body. In most patients, such displacement interactions rarely produce more than a short-lived effect. However, for the neonate with reduced renal and hepatic excretion, it may be relevant in a small number of drugs.

Enzyme induction

Many drugs are metabolised in the liver. Induction of the hepatic microsomal enzyme system by one drug may increase the rate of metabolism of another drug. This may result in lowered plasma concentrations of the second drug and potentially a reduced effect.

An example is the increase in the metabolism of corticosteroids such as dexamethasone by phenobarbital. This results in a reduction of the steroid plasma concentration and consequently reduced clinical effectiveness. The steroid dose will need to be increased to produce the desired clinical response.

Discontinuation of a drug known to induce hepatic enzymes may result in increased serum concentrations of a second drug, with toxicity as a result. Care must therefore be taken when discontinuing enzyme-inducing agents, as dose reduction of interacting drugs may be necessary. Phenobarbital, phenytoin, carbamazepine and rifampicin are examples of important enzyme-inducing agents.

Table 24.6 Major drug interactions

DRUGS	TYPE OF INTERACTION	EFFECT
Midazolam + morphine	Pharmacodynamic	Increased sedation
Indometacin + gentamicin	Renal excretion	Increased risk of nephrotoxicity
Erythromycin + cisapride	Enzyme inhibition	Decreased metabolism of cisapride → ↑ risk of toxicity
Erythromycin + midazolam	Enzyme inhibition	Decreased metabolism of midazolam → ↑ sedation
Ceftriaxone + calcium salts	Precipitation	Death. Precipitation in heart and lungs of ceftriaxone–calcium salts

Enzyme inhibition

Drugs that inhibit hepatic microsomal enzymes may result in reduced metabolism of other drugs and therefore raised serum concentrations, with potential for increased effect and toxicity. These are usually the most dangerous type of drug interactions. Erythromycin, cimetidine, ciprofloxacin and fluconazole are examples of common enzyme inhibitors.

Erythromycin inhibits the metabolism of midazolam, resulting in markedly increased plasma midazolam concentrations with accompanying profound sedation. Dose reductions are necessary to avoid toxicity and may need to be of the order of 50–75%.

Cimetidine inhibits the metabolism of phenytoin, with a resulting increase in plasma concentrations of the anticonvulsant and the potential for toxicity. Metronidazole may also have the same effect on phenytoin levels in some patients. It is necessary to monitor the phenytoin levels carefully and make careful dose adjustments as needed.

Renal excretion

Many drugs are renally excreted through glomerular filtration and active tubular secretion. Some drugs are actively transported across the kidney tubules and competition for such active transport mechanisms may occur. This can result in delayed excretion of competing drugs. Similarly, the concomitant administration of indometacin and aminoglycoside antibiotics, such as gentamicin, may result in drug toxicity. Indometacin reduces glomerular filtration in the kidney, the main route of elimination for these antibiotics. This may result in retention of the antibiotic, with consequential high levels and the potential for both renal toxicity and ototoxicity.

Drug therapy for the fetus

Improved diagnostic methods during pregnancy have led to the development of drug interventions for fetal disorders diagnosed in utero.

Corticosteroids in preterm labour

A frequently seen example is the use of corticosteroid therapy in mothers threatening preterm labour. The Cochrane review in 2006, of trials using corticosteroid drugs for women expected to deliver prematurely, showed that a single course of corticosteroid significantly reduces neonatal death and morbidity (Roberts and Dalziel 2006). Weekly courses do not confer a benefit over a single course (Guinn et al. 2001).

Antiarrhythmic agents in fetal tachycardia

Intrauterine development of sustained fetal tachycardia and congestive heart failure is a life-threatening condition requiring urgent treatment. Treatment of the fetal arrhythmias by giving drugs to the mother can be successful. Drugs used include digoxin, quinidine, verapamil, flecainide, propafenone, propranolol, procainamide, amiodarone and sotalol. This wide range of drugs suggests that the search for optimal therapy of this condition is still ongoing. Digoxin and flecainide have been the most commonly used agents, but sotalol may also be a valuable treatment option in some circumstances (Oudijk et al. 2000).

Antiretroviral therapy to prevent vertical transmission of HIV

There is an increasing prevalence of women infected with human immunodeficiency virus (HIV) and they now account for almost half the annual incidence of infections. Most of these women are of childbearing age and it has been estimated that they transmit the infection to their babies at a rate of around 1500 cases per day worldwide.

Complex regimens combining antepartum, intrapartum and postpartum administration of antiretroviral therapy together with prudent use of caesarean section can reduce transmission of infection from mother to baby to 0–2.8% (Ch. 39.2) (Grosch-Wörner et al. 2000). Zidovudine has been the drug used in most of the studies. Nevirapine and lamivudine have also been studied.

Unfortunately, expensive and complicated drug therapy is unlikely to be practical in many parts of the world where the rates of HIV infection are at their highest. Work is ongoing to evaluate the benefit of simpler, cheaper and more practical methods of drug delivery in these areas.

Endocrine disorders

Other conditions such as congenital adrenal hyperplasia and fetal thyroid disorders have also been treated by maternal administration of drugs. This field of therapeutics is an exciting and developing area, which requires more research in the future.

Drugs in breast milk

Breastfeeding has significant advantages for both the infant and the mother. It is associated with a significant reduction in both morbidity and mortality in the infant and is therefore to be encouraged. Decisions to limit a mother's breastfeeding must be justified by the fact that the risk to the baby clearly outweighs the benefits (Ito 2000). Consideration must be given to how much drug is excreted into the milk, and the risk of this amount to the baby.

Risk of drug toxicity in breastfed infants

The risk of an adverse drug reaction following breastfeeding by a mother taking medicines is small. A prospective study of over 800 infants who were being breastfed by women taking regular medicines detected no major adverse drug reactions (Ito et al. 1993). Just over 10% of mothers reported a minor adverse drug reaction in the infant (diarrhoea, drowsiness or irritability were the most frequent). This important study emphasises the safety of breastfeeding in mothers requiring medicines, although a note of caution is required regarding over-the-counter codeine-containing analgesia. One mother who was an ultrarapid metaboliser of codeine to morphine had high levels of morphine in her breast milk, which may have contributed to the cot death of her baby (Koren et al. 2006).

The following drugs – cytotoxics, ergotamine, immunosuppressants, lithium and phenindione – are contraindications for breastfeeding. Additionally, there are a group of medicines that may potentially cause problems during breastfeeding (Table 24.7). It is advisable to discuss management with the local paediatric clinical pharmacist or the local drug information centre for a risk/benefit assessment.

Breast milk is produced while the infant is suckling. The breast stores only a small amount of milk between feeds. Because of this, the timing of drug doses in relation to feeds is important in

determining how much drug will pass to the baby. If it is possible for the mother to time taking the dose immediately after a feed, then her drug serum concentration will be at the lowest when the baby next feeds, which means that the minimal amount will be transferred to the milk and the baby. It is however clearly difficult to control this completely if a baby is suckling every couple of hours. See [Weblink](#) section for the website of the UK Drugs in Lactation Advisory Service.

Therapeutic drug monitoring

Therapeutic drug monitoring (TDM) has been defined as 'the measurement of drug concentrations in biologic fluids to assess whether they correlate with the patient's clinical condition and whether the dosage or dosage intervals need to be changed' (Soldin and Soldin

2002). The purpose is to optimise the management of patients receiving drug therapy for the treatment or prevention of disease.

For TDM to aid in drug therapy, the following criteria must be satisfied (Soldin and Soldin 2002):

- clinically interpretable correlation between serum drug concentration and pharmacodynamic effect
- narrow margin (therapeutic index) between serum concentrations causing toxic effects and those producing therapeutic effect
- serum concentration produced by a given dose is unpredictable because of inter- and inpatient pharmacokinetic differences
- pharmacodynamic effects of the drug are not easily measurable
- a rapid and reliable method for drug serum concentration analysis must be available.

The drugs that require TDM in neonates are shown in [Table 24.8](#). The timing of blood sampling for analysis is important. Steady state should be reached before levels are taken, unless, of course, toxicity is suspected before this time. It takes three to four half-lives of the drug to reach steady state. For a drug such as phenobarbital that has a $t_{1/2}$ of around 2–4 days in the neonate, steady state will not be achieved until after 1–2 weeks of treatment. Steady state can be achieved more quickly using a loading dose. A further complicating factor in neonates is the rapidly changing pharmacokinetic capacity of these patients. The significant improvements in renal and hepatic elimination mechanisms after birth may mean steady state is never achieved for drugs given in the neonatal period.

Therapeutic ranges

Recommended therapeutic ranges for drugs are usually based on adult data. Hospital laboratories tend to quote the same reference ranges irrespective of the age of the patient. This leads to the assumption that patients of all ages respond in the same way to similar blood levels. This is unlikely to be the case, as receptor numbers and sensitivities may be different, and the drug concentration reaching the receptor sites in patients of different ages is also likely to vary, owing to altered pharmacokinetic handling. The therapeutic range for phenobarbital has been shown to be higher in the neonate than in older children and adults.

Table 24.7 Drugs that may cause problems during breastfeeding

GROUP	DRUGS
Anticonvulsants	Ethosuximide, lamotrigine, phenobarbital, primidone
Antidepressants	Doxepin, fluoxetine
Antibiotics	Chloramphenicol, metronidazole
Anxiolytics	Alprazolam, diazepam
Antihypertensives	Acebutolol, atenolol, nadolol, sotalol
Antiarrhythmics	Amiodarone
Antipsychotics	Chlorpromazine, haloperidol
Bronchodilators	Theophylline
Radioisotopes	–
Non-medicinal	Alcohol, amphetamine, cocaine, coffee, heroin, marijuana, phencyclidine

Table 24.8 Neonatal drugs that require monitoring

DRUG	WHEN TO SAMPLE	THERAPEUTIC RANGE
Amikacin	Predose (trough): just prior to next dose Postdose (peak): 1 hour after an IV dose	Trough level < 8 mg/l Peak level 20 mg/l
Digoxin	At least 6 hours after dose	0.8–2.2 µg/l
Gentamicin/tobramycin	Predose (trough): just prior to next dose Postdose (peak): 1 hour after an IV dose	Trough level <2 mg/l (preferably <1 mg/l) Peak level 5–10 mg/l
Phenobarbital	Immediately prior to next dose	20–40 mg/l
Phenytoin	Immediately prior to next dose	6–15 mg/l
Vancomycin*	Predose (trough): immediately prior to next dose	Trough level 5–15 mg/l (15–20 mg/l for less sensitive strains of MRSA)

*There is controversy regarding the value of measuring peak levels of vancomycin, as there is no evidence that transiently high peak levels cause toxicity. MRSA, methicillin-resistant *Staphylococcus aureus*.

Neonates have reduced levels of plasma proteins, and those plasma proteins have a reduced affinity and capacity to bind drugs. This means that drugs which are normally highly protein-bound will be less so in the neonate, resulting in a higher free – and, therefore, active – fraction of drug. Levels are usually reported in terms of total concentration; hence the same level in a neonate and an adult may produce very different effects in terms of efficacy and toxicity.

Difficulties in relation to TDM in the neonate also occur with the presence of interfering endogenous compounds that may not be present in adult patients. Digoxin-like immunoreactive substances may be present in neonates. These cross-react with many digoxin assay methods, falsely elevating total serum drug concentrations (Soldin and Soldin 2002). It is possible that other compounds interfering with other drug assays may be found in the future.

Introduction

Pain has been described as 'an unpleasant sensory and emotional experience which is usually associated with tissue damage or described in terms of such damage'. While neonates have a broadly similar type of response to painful stimuli as adults, the presence or absence of pain as a conscious event can never be proven. Infants and neonates have only a limited ability to communicate compared with adults, and their responses can be inconsistent or absent (Marshall et al. 1980). Much depends on the nature of self-awareness, consciousness and the development of 'self' in fetal life (Glover and Fisk 1996; Lloyd-Thomas and Fitzgerald 1996; Szawarski 1996). Given the impossible task of making judgements on the nature of pain perception in the fetus and neonate, the term 'nociception' (the anatomical and physiological system of pain sensation) has been felt to be more appropriate.

Despite increasing interest in provision of analgesia to the neonatal population there is evidence that procedural pain is poorly managed (Johnston et al. 1997). Moreover, this is not a small problem: neonates, particularly those who are unwell, are subjected to a large number of nociceptive stimuli. A total of 500 invasive procedures were recorded in one neonate during a single hospital stay, and this is not unusual (Barker and Rutter 1995). The American Academy of Pediatrics has produced a policy statement on the prevention and management of neonatal pain which emphasises that painful procedures are a very common part of routine neonatal care (Batton et al. 2006).

Nociception in the infant

Nociceptive pathways begin to develop as early as 6 weeks' gestation when dorsal horn cells in the spinal cord have formed synapses with the developing sensory neurons (Okado 1981). These sensory neurons grow peripherally to reach the skin and mucosal surfaces by 20 weeks (Humphrey 1964; Valman and Pearson 1980). At full term the density of cutaneous nociceptive nerve endings is at least as great as that of the adult (Gleiss and Stuttgart 1970). Organisation of the laminar structure of the cells in the dorsal horn, and their synapses, and the appearance of specific neurotransmitter vesicles begins at 13 weeks and is completed by 30 weeks (Rizvi et al. 1986). By this time, nerve tracts associated with nociception are fully myelinated up to the thalamic level (Gilles et al. 1983). Synaptic connections of the thalamocortical tracts occur at 24 weeks' gestation (Kostovic and Rakie 1984), and myelination of the nociceptive thalamocortical radiations is complete by 37 weeks (Gilles et al. 1983). Other nociceptive tracts may not be fully myelinated until much later (Anand and Carr 1989), but lack of myelination does not imply lack of function. Synaptic connections of C-fibres do not appear to mature functionally until the third trimester but noxious stimuli can still be transmitted via A- β fibres (Fitzgerald et al. 1994). Descending inhibitory tracts, which act via inputs into spinal cord cells to suppress the transmission of noxious stimuli, are also not fully functional at term. The lack of descending inhibition from higher centres will tend to increase afferent nociceptive transmission in the spinal cord.

Few neurophysiological or cytochemical studies have been attempted in the human infant. Positron emission tomography has shown that glucose utilisation, and by inference cerebral

metabolism, is maximal in sensory areas of the neonatal brain (Chugani and Phelps 1986) and that auditory and visual evoked potentials have developed by 30 weeks' gestation (Henderson-Smart et al. 1983). These data, along with electroencephalograph data (Torres and Anderson 1985), imply a very complex level of integration and maturity within the cerebral cortex by this time. Somatosensory evoked responses are present from 28 weeks' gestation, although the latency is long, owing to slow peripheral and central transmission. Studies using functional near-infrared spectroscopy (fNIRS) have demonstrated haemodynamic changes related to clinical noxious stimuli (heel lance (Slater et al. 2006) and venesection (Bartocci et al. 2006)) in the sensory cortex of newborns as young as 25 weeks' gestation. These responses are diminished during sleep (Slater et al. 2006). Slater et al. (2009a) have also used event-related evoked potentials to demonstrate cortical responses to heel lance.

While nociceptive connections remain immature in the preterm neonate, the larger receptive fields, the immaturity of the descending inhibitory pathways, and the ability of non-C-fibres to transmit nociceptive inputs into the dorsal horn facilitated by subthreshold C-fibre effects give the impression of an underdamped, poorly discriminative system with a potential for much exaggerated responses. This is borne out in the observations of Fitzgerald et al. (1989) and Andrews and Fitzgerald's (1994) on the cutaneous withdrawal reflex and other studies which have shown that newborn reactions to painful stimuli can be diffuse, unlocalised or sometimes completely absent (Marshall et al. 1980). This failure to respond consistently to a standard noxious stimulus can confound attempts to quantify pain using behavioural measurement.

Effects of nociception

The initial effects of nociception can be categorised under physiological, stress and behavioural responses. All of these responses can compromise the physiological stability of a neonate receiving intensive care.

Haemodynamic responses to noxious stimuli occur as early as 18 weeks' gestation in the human fetus (Teixeira and Fogliani 1996). Neonates undergoing awake nasotracheal intubation have a rise in mean arterial pressure of 57% with a similar rise in intracranial pressure during the procedure (Kelly and Finer 1984). Age-related differences in cardiovascular responses to noxious stimuli have been reported (Porter et al. 1991). In a study on lumbar puncture in preterm infants, the less mature babies (<32 weeks' gestational age) showed the greatest rise in blood pressure during the handling phase rather than during the actual procedure. This was in contrast to the more mature babies, who displayed maximum response during the procedure itself. Other physiological responses that have been investigated in the context of nociception are R-to-R interval and frequency analysis on electrocardiogram (Porter et al. 1988), transcutaneous oxygen tension, ventilatory patterns and sweating.

Hormonal responses to noxious stimuli can also be identified in the human fetus and the response obtunded by opioids (Fisk et al. 2001). Neonatal stress responses to surgery appear to be greater in magnitude and shorter-lived than in older infants (Anand 1990; Okur et al. 1995) and the subsequent nitrogen loss appears to be greater in the younger age groups. Inadequate suppression of these responses during major surgery affects postoperative recovery (Anand et al. 1987), but it remains unclear if complete elimination of the responses is desirable either. Some measure of stress response during surgery can be achieved by real-time analysis of blood sugar provided glucose-containing solutions are avoided (Wolf et al. 1998).

Preterm infants exhibit hypersensitivity and postinjury hyperalgesia following heel lancing, which can be prevented by the application of local anaesthetic (Fitzgerald et al. 1989). There is also evidence that early tissue injury can cause hyperinnervation (increased branching of nociceptive nerve endings), which persists and may lead to hyperalgesia and allodynia (Constantinou et al. 1994).

The impression that emerges is that even the very preterm infant has complex interneuronal connections capable of integrated responses to tactile or nociceptive input. They have inconsistent responses to external stimuli, which may reflect the late functional connections of sensory afferents (particularly C-fibres) within the spinal cord. However, the combination of larger receptive fields, recruitment of non-nociceptive afferents and reduced inhibitory controls results in 'underdamped' responses (long-lasting, exaggerated and poorly localised) once afferent stimuli have achieved central activation above a threshold level. Inconsistency of response may reflect the profound effects that conscious state (Grunau and Craig 1987) and other external responses (Haouari et al. 1995) have on behaviour.

Secondary effects of nociception

Neonates who experience repeated noxious stimuli can show both short-term hypersensitivity (Fitzgerald et al. 1989) and longer term persistence of immature pain responses (Johnston and Stevens 1996). Preterm infants have been shown to have increased cortical responses to heel lancing than term born controls (Slater et al. 2010a). At 18 months they have been reported to respond less than normal infants to everyday painful experiences (Grunau et al. 1994), and at 4–5 years show increased somatisation (an inappropriate expression of psychosocial distress as physical symptomatology). Awake circumcision without analgesia causes irritability, reduced attentiveness and poor orientation that can last longer than the expected duration of pain (Dixon et al. 1984), and 3–6 months later circumcised infants have exaggerated responses to painful stimuli compared with a matched group who have not been circumcised (Taddio et al. 1997).

Comforting strategies that reduce the stress of interventional procedures in preterm infants are associated with improved developmental and clinical outcomes (Als et al. 1986). The results of the multicentre NOPAIN trial evaluated the risks and benefits of providing analgesia to ventilated neonates. A low-dose morphine infusion was found to reduce the incidence of neurological complications (intraventricular haemorrhage and periventricular leukomalacia) in ventilated infants when compared with midazolam or dextrose (Anand et al. 1999). The subsequent larger NEOPAIN trial raised concerns about the risk of severe intraventricular haemorrhage, periventricular leukomalacia and death in those who received boluses of morphine (Anand et al. 2004). Although later analysis of these data demonstrated that the risk of intraventricular haemorrhage was associated with morphine rather than causal (Hall et al. 2005), there have been ongoing concerns about the liberal use of opioids and induction of apoptosis in the developing brain (Hu et al. 2002), increase of longer term responses to painful stimuli (McRae et al. 1997) and an association with self-destructive behaviour in adolescence (Jacobson et al. 1987).

Measurement of pain/nociception in the neonate

Most of the early studies on infant pain measurement were based on a single noxious stimulus such as heel prick (procedural pain)

Table 25.1 Modified observational pain scale

AGITATION	FACIAL EXPRESSION	MOVEMENT	VENTILATION
2 = Major	2 = Grimace/ nasal flare	2 = Flexed/tense	2 = Fighting ventilator
1 = Responds to comforting	1 = Movement	1 = Appropriate	1 = Comfortable
0 = No movement	0 = No movement	0 = No movement	0 = Apnoea

A modified observational pain scale used on the paediatric intensive care unit in the Bristol Royal Hospital for Children. Hourly observations are recorded. A total score of 2 or less implies oversedation, 3–5 is ideal and 6 or more implies undersedation.

and were primarily developed for research purposes. This was a useful model because it provided a relatively consistent stimulus from which to identify and grade responses. However, the behavioural tools derived from studies on procedural pain have limited applicability to other situations such as postoperative pain and the discomfort from prolonged immobility in the neonatal intensive care unit. There are few validated tools for prolonged pain or discomfort, they require training to increase reliability and are labour-intensive with a low degree of clinical utility. The Bristol Royal Hospital for Children uses a modified observational pain scale that is simple to use, requires minimal training and is feasible in a clinical setting (Table 25.1). The tools available are either unidimensional, using behavioural responses to pain, or multidimensional, using a combination of behavioural, physiological and contextual indicators. Behavioural indicators are more specific than physiological changes in all age groups. Many of these tools are developed from validated techniques used in older children and infants, such as the Children's Hospital of Eastern Ontario Scale. Scales such as the Premature Infant Pain Profile (PIPP) have adjustments for gestational age and sleep state, as an acknowledgement that these alter the measurable responses to pain (Stevens et al. 1996). In the paralysed neonate behavioural tools cannot be used and physiological measures such as cardiovascular responses to handling have to be used.

Table 25.2 shows some of the commonly used pain-scoring systems as described by Anand et al. (2006). The Royal College of Nursing (UK) has published an algorithm for selecting the most appropriate pain scale for specific clinical situations, as well as guidelines for recognition and assessment of acute pain in children (see Weblinks).

There is no 'gold-standard' pain scale, as it is not possible to correlate scores with preverbal infants' pain experience. However Slater et al. (2008) have demonstrated a positive correlation of the cortical response measured by fNIRS in term neonates with the PIPP score. The correlation is strongest with the facial (behavioural) rather than the physiological components. However, there are several occasions when the newborns had zero PIPP scores when subjected to heel lances, but had measurable cortical responses. Therefore while pain scoring is the best clinical tool available at the present time, it may underestimate the cortical response, especially in the most preterm (Slater et al. 2009b) and sick infants.

Pharmacological considerations

Classically, neonates are regarded as highly susceptible to drugs, particularly opioids, in terms of both pharmacodynamics (physiological effects of the drug on the body) and pharmacokinetics (how the body handles the drug). However, the limited studies available have shown that there is large individual variability in this

population associated with maturity, previous exposure to drugs and organ function. Individual drug effects from dosing regimens are therefore poorly predictive and can only be described in general terms.

Pharmacodynamics

Opioid receptors change both in numbers and in receptor type during development and in the rat this is associated with a large change in sensitivity (Pasternak et al. 1980). It has been suggested from human studies that have compared plasma concentrations of opioid drugs that human neonates could be relatively resistant to the ventilatory effects of opioids, and that the sensitivity observed after opioid administration is due to selective distribution of the drug to the brain after administration. Lipid-soluble drugs, such as fentanyl, are preferentially redistributed into the neonatal brain after a bolus injection and attain high initial peak concentrations at the effect site (biophase). In contrast, elimination of the drug from biophase is slow because of the limitations on peripheral uptake and drug elimination. Fat-soluble opioids such as fentanyl will therefore have a more rapid onset of effect, greater potency and slower offset than can be predicted by simply analysing pharmacokinetic data. Delivery of morphine into biophase may also be enhanced in the neonate and young infant owing to immaturity of the blood-brain barrier (Kupferberg and Way 1963).

Pharmacokinetics

Neonates have a high percentage of body water and less fat than older infants. Consequently, relatively large loading doses of water-soluble drugs such as morphine may need to be given over the first few hours of an infusion to achieve adequate plasma concentrations and effect. Subsequent drug elimination in the 'drug-naïve' neonate is delayed due to immaturity of hepatic and renal function. Therefore, once steady state has been achieved infusion rates need to be reduced substantially to prevent accumulation.

A fourfold reduction in the elimination half-life of morphine takes place in the first few years of life, with mean values of 7.2 hours below 1 month, compared with 1.7 hours in adults (McRorie et al. 1992). This is due primarily to the prolonged clearance of the drug. However there is wide individual variability between subjects, particularly in the neonate. The mean elimination half-life in the newborn was measured at 13.9 hours with a standard deviation of 6.4 hours (Olkolo et al. 1988). Pharmacokinetic data for fentanyl show a similar pattern with even greater variability in the premature infant (Collins et al. 1985; Koehntop et al. 1986; Gauntlett et al. 1988). Hepatic clearance of fentanyl may be drastically reduced in neonates undergoing intra-abdominal surgery or those with raised intra-abdominal pressure (Koehntop et al. 1986).

Table 25.2 Commonly used measures of pain in neonates

MEASURE	VARIABLES INCLUDED	TYPE OF PAIN	PSYCHOMETRIC TESTING
Premature Infant Pain Profile (PIPP) (Slater et al. 2009b)	Heart rate Oxygen saturation Facial actions Takes state and gestational age into account	Procedural Postoperative (minor)	Reliability, validity, clinical utility well established
Neonatal Infant Pain Score (NIPS) (Anand et al. 2006)	Facial expression Crying Breathing patterns Arm and leg movements Arousal	Procedural	Reliability Validity
Neonatal Facial Coding System (NFCS) (Anand et al. 1987)	Facial actions	Procedural	Reliability, validity, clinical utility, high degree of sensitivity to analgesia
Neonatal Pain, Agitation and Sedation Scale (N-PASS)	Crying Irritability Behavioural state Facial expression Extremity tone Vital signs	Postoperative Procedural Ventilated	Reliability, validity, includes sedation end of scale, does not distinguish pain from agitation
Cry, Requires oxygen, Increased vital signs, Expression, Sleeplessness (CRIES) (Slater et al. 2008)	Crying Facial expression Sleeplessness Requires oxygen to stay at >96% saturation Increased vital signs	Postoperative	Reliability Validity
COMFORT scale (Stevens et al. 1996)	Movement Calmness Facial tension Alertness Respiration rate Muscle tone Heart rate Blood pressure	Postoperative Critical care Developed for sedation Recently validated for postoperative pain in 0–3-year-old infants	Reliability Validity Clinical utility

(Modified from Anand et al. (2006).)

This has been attributed to the effects of raised intra-abdominal pressure on liver blood flow (Masey et al. 1985). The implications for infants undergoing abdominal surgery are clear: some infants will have a sustained effect from doses of opioid that would normally be expected to have a limited duration of action.

Clinical analgesia

Opioids and paracetamol remain the most commonly used analgesics but there is increasing use of ketamine (an *N*-methyl-D-aspartate (NMDA) antagonist), clonidine (α_2 agonist), local anaesthetics and non-steroidal anti-inflammatory drugs (NSAIDs).

Opioids

Morphine, fentanyl and codeine are the most commonly used opioids in the UK. All can cause ventilatory depression, hypotension, urinary retention and decreased intestinal motility leading to delayed feeding after abdominal surgery.

Morphine remains the historical gold standard with which other analgesics are compared. Morphine has both slower onset and offset than fentanyl after a single dose, but after long-term infusion this effect is reversed because of the shorter terminal elimination half-life of morphine. In the ventilated neonate, an intravenous loading dose (50–150 $\mu\text{g/kg}$) is required to achieve effective analgesia, followed by an infusion rate between 5 and 20 $\mu\text{g/kg/h}$. However as tolerance develops, the infusion rate may need to be further increased. Nurse-controlled analgesia (NCA) is a useful technique for control of infant pain. The baby receives a background morphine infusion (2.5–10 $\mu\text{g/kg/h}$) topped up at appropriate intervals by 'nurse-controlled' doses (varying from about 2.5 to 10 $\mu\text{g/kg}$) according to formal pain assessment.

Morphine should be used with caution in the spontaneously breathing postoperative neonate. Loading doses of 10–50 $\mu\text{g/kg}$ morphine can be given by slow infusion over 15 minutes in conjunction with sedation scores at 5-minute intervals. Once the desired level of comfort has been achieved, the infusion is discontinued, even if the full dose has not been delivered. Additional

doses are then given in the same fashion according to regular documented pain scores, thereby maintaining a therapeutic level on an individual titrated basis. NCA can also be used with a low background morphine infusion (1–5 µg/kg/h). All infants under 6 months receiving opioids need to stay in a high-dependency unit for continual monitoring with direct observation, pulse oximetry and ventilatory monitoring.

Fentanyl provides intense analgesia and relative cardiovascular stability. At high doses (50–150 µg/kg as a single injection), it can control pulmonary hypertension (Hickey 1985). These doses are well above analgesic doses (0.5–10 µg/kg). Fahnenstich and colleagues (2000) observed chest wall rigidity in 8 out of 89 neonates following relatively small doses of 3–5 µg/kg fentanyl, all cases responded quickly to either naloxone or neuromuscular blockade. The high lipid solubility of fentanyl and increased skin permeability of the preterm neonate make transdermal administration a feasible route of administration, which is currently being evaluated. Trans-tracheal fentanyl provides rapid absorption in rabbits but awaits clinical trials in humans (Irazuzta et al. 1996).

Remifentanyl is eliminated by the action of plasma esterases and consequently is not dependent on immature hepatic metabolic processes. It is cleared rapidly and predictably, thereby making it an attractive drug for short neonatal surgery when rapid recovery is needed (Berde et al. 2005). It has been used to good effect for sedation during mechanical ventilation – doses of up to 0.1 µg/kg/min provided adequate sedation in most infants (Giannantonio et al. 2009) – and provides good conditions when used with suxamethonium for tracheal intubation. There is emerging evidence of its efficacy and safety when used to provide intraoperative analgesia in major neonatal surgery (Michel et al. 2008; Marsh and Hodgkinson 2009).

Codeine has, reputedly, a lower incidence of opioid-related side-effects. It has been advocated for use in neonatal practice at a dose of 1 mg/kg orally/intramuscularly/rectally. Single-dose administration appears safe but with repeated doses unwanted side-effects do occur (Reisime and Pasternak 1996). Codeine is metabolised to morphine, but there is considerable variability, and in a small genetic subgroup of 'poor metabolisers' (9% in UK, 30% in Hong Kong Chinese) codeine has virtually no analgesic effect (Williams et al. 2001). This large interpatient variability necessitates caution when using codeine for long-term use in neonates.

Tolerance and withdrawal

While initial doses of opioid infusions needed for analgesia and sedation are low, the dose requirements increase rapidly. Neonates undergoing extracorporeal membrane oxygenation require five times the initial opioid infusion rate by day 6 to achieve the same level of sedation due to a combination of enhanced elimination (Arnold et al. 1991) and true tolerance (Greeley and Debruijn 1998). The use of long-term infusions of morphine for sedation alone is debatable: it is better to reserve analgesic drugs for pain relief or use low-dose infusions of morphine in conjunction with other long-acting sedatives such as chloral hydrate or promethazine.

Opioid antagonists (naloxone 4–10 µg/kg) easily reverse opioid side-effects but must be used with caution with neonates receiving opioid infusions as acute antagonism may trigger a syndrome of withdrawal. Withdrawal is characterised by an excitation of the central nervous system, the gastrointestinal system and the autonomic nervous system (Suresh and Anand 1998). Opioid abstinence syndrome can occur after 48 hours of morphine infusion but is more usually observed after 4–5 days. Management includes the use of a reducing opioid regimen (with morphine or methadone), α_2 antagonists (clonidine 3–5 µg/kg 8–12-hourly) and benzodiazepines for anxiolysis. Weaning schedules can last weeks. Preventive methods

include the judicious use of opioids combined with formal comfort scores to optimise the rate of opioid withdrawal.

Non-opioids

Paracetamol (acetaminophen) is primarily metabolised by glucuronidation in older children but by sulphation in neonates (van Lingen et al. 1999). Once the main metabolic pathways are saturated paracetamol is oxidated by the cytochrome P450 system to a reactive intermediary compound which is bound to glutathione, but can react with hepatocyte macromolecules in the absence of glutathione. Neonates may have some protection from the hepatic toxicity effects of paracetamol by having greater glutathione stores and slower oxidative metabolism (Truog and Anand 1989). Paracetamol is a widely accepted treatment for moderate pain in neonates. Current data suggest that its short-term use in term and preterm neonates is safe and efficacious (Anand et al. 2000). It has additive effects when combined with opioids thereby allowing lower doses and subsequently lower incidence of side-effects (Menon et al. 1998). Loading doses of paracetamol are similar for premature and term neonates (25 mg/kg orally or 35 mg/kg by triglyceride suppository). Subsequent maintenance regimens must be tailored to the maturity of the infant. Anderson et al. (2002) found that adequate plasma concentrations can be achieved by an oral dose of 25 mg/kg/day in premature neonates at 30 weeks post-conception, 45 mg/kg/day at 34 weeks' gestation, 60 mg/kg/day at term, and 90 mg/kg/day at 6 months of age. Rectal doses must be increased by a third the oral dose to account for the decreased absorption by this route. These regimens may cause hepatotoxicity in some individuals if used for longer than 2–3 days.

Intravenous paracetamol is available but there is much international discussion as to the safe and most efficacious dose when used in the neonatal population. In the UK it is currently licensed for use in infants aged over 10 days, and less than 10 kg, at a dose of 7.5 mg/kg, not exceeding 30 mg/kg/day; however many paediatric anaesthetists are using higher doses (Wilson-Smith and Morton 2009). This dosing does not take into consideration maturational changes in paracetamol metabolism or the evidence that intravenous paracetamol can be given to premature infants and those under 10 days if an appropriately reduced dose is administered. In Australia 15 mg/kg 6-hourly is administered to term infants over 10 days' age with a reduced dose of 7.5 mg/kg 6-hourly in term infants under 10 days (Anderson and Allegaert 2009). Further investigation is needed to establish the safety of intravenous paracetamol in premature neonates.

NSAIDs have antipyretic and anti-inflammatory properties with no respiratory depressant or sedative side-effects. As with paracetamol, they have an opioid-sparing effect in older children. Concern over potentially serious side-effects has limited NSAID use for analgesia. Current knowledge of their neonatal effect results almost entirely from their use in the treatment of patent ductus arteriosus (PDA). Side-effects of indometacin include oliguria from decreased renal perfusion; necrotising enterocolitis and gut perforation from decreased splanchnic perfusion (Shorter et al. 1999); and gastrointestinal bleeding from reduced platelet function. Decreased cerebral blood flow may have a preventive effect on intraventricular haemorrhage in preterm neonates (Ment et al. 1996). Ibuprofen has been used as an oral analgesic in term neonates and has a lower incidence of side-effects than indometacin when used for treatment of PDA (Van Overmeire et al. 2000). It should be used with caution in jaundiced patients as it may displace bilirubin from albumin and, at a dose of 5–10 mg/kg, ibuprofen need only be repeated every 12–24 hours as its half-life is prolonged compared with that in adults (Aranda et al. 1997).

Over the last decade there has been a resurgence of interest in ketamine and clonidine. Ketamine is a centrally acting NMDA receptor antagonist and potent analgesic. It has been used with proven efficacy and safety for the anaesthesia of neonates for some years. It can be given intravenously (0.5–2 mg/kg), rectally (3–8 mg/kg), intramuscularly (2–5 mg/kg) and via the neuroaxial route (Pellier et al. 1999). It has the advantage of promoting cardiovascular stability, especially in hypovolaemic patients; it maintains respiratory drive and is a bronchodilator. It increases salivation and respiratory secretions and is usually given with an anticholinergic agent (e.g. atropine 10 µg/kg iv) and is often combined with midazolam (e.g. 25 µg/kg) to provide procedural analgesia and sedation. Intravenous doses of 2 mg and intramuscular doses of 3 mg/kg have been found to induce sedation in 45 seconds and 4 minutes respectively (Cotsen et al. 1997). S(+)-ketamine, one of the two enantiomers of ketamine, has threefold greater analgesic potency than racemic ketamine and may prove to have fewer side-effects. It has been used effectively in caudal anaesthesia (Marhofer et al. 2000) but further clinical trials are needed to evaluate its parenteral use in neonates.

Clonidine is an α_2 agonist that is commonly used via the caudal route (1–2 µg/kg) in combination with local anaesthetic drugs. It

provides dose-dependent analgesia following oral and intravenous administration. It has the advantage of having less respiratory depression than opioids, although there are case reports of post-operative apnoea in term and preterm infants (Breschan et al. 1999; Bouchut et al. 2001). Oral doses of up to 4 µg/kg 8-hourly have been used in the treatment of neonatal opioid withdrawal (Suresh and Anand 1998).

Pure sedative drugs have an adjuvant role in the treatment of neonatal pain. In combination with analgesics, they may reduce anxiety and stress by promoting sleep. Of the benzodiazepines, lorazepam (20–100 µg/kg) has a longer duration, resulting in a smoother sedative effect (McDermott et al. 1992). Benzodiazepines have an additive effect on the respiratory depression of opioids. Chloral hydrate, promethazine and triclofos sodium are other popular sedative drugs.

Local anaesthetics

The use of local and regional anaesthesia/analgesic techniques has a significant, albeit specialised, role in the treatment of neonatal pain (Table 25.3). High-dose opioid techniques may be beneficial to the sick neonate by suppressing nociceptive processing

Table 25.3 Analgesic doses

POPULATION		DOSE	NOTES
Morphine	Ventilated neonate	50–150 µg/kg iv	Loading dose
	Unventilated neonate	5–20 µg/kg/h iv 2.5–10 µg/kg iv 2.5–10 µg/kg/h iv 10–50 µg/kg iv	Infusion NCA (bolus every 30 min) NCA (background infusion) Slow loading dose
Fentanyl	For ventilated neonates only	0.5–10 µg/kg iv	
Alfentanil	For ventilated neonates only	5–10 µg/kg iv 0.5–1 µg/kg/h iv	Loading dose Infusion
Codeine		1 mg/kg po/pr	
Paracetamol	All ages	25 mg/kg po, 35 mg/kg pr	Loading dose
	30 weeks PCA	25 mg/kg po, 30 mg/kg pr	Maximum daily dose
	34 weeks PCA	45 mg/kg po, 60 mg/kg pr	Maximum daily dose
	40 weeks PCA	60 mg/kg po, 80 mg/kg pr	Maximum daily dose
	60 weeks PCA	90 mg/kg po, 120 mg/kg pr	Maximum daily dose
Paracetamol	Term neonates <10 days	30 mg/kg iv	Maximum daily dose
	Term neonates >10 days	60 mg/kg iv	Maximum daily dose
Ibuprofen		5–10 mg/kg po	Every 12–24 hours
Ketamine		0.5–2 mg/kg iv*	Coadministration with an anticholinergic advised due to increased respiratory secretions
		3–8 mg/kg pr	
Clonidine		2–4 µg/kg po	For opioid withdrawal
Lorazepam		20–100 µg/kg iv	
Chloral hydrate/ triclofos sodium		30–50 mg/kg po/pr	
Promethazine		0.5 mg/kg iv/po	
Doses of commonly used analgesic and sedative drugs. These dosing regimens are guides only and care must be taken as there is considerable variation in effect. NCA, nurse-controlled analgesia; iv, intravenous; po, orally; pr, per rectum; PCA, postconceptual age. *2 mg/kg ketamine is an anaesthetic dose and may cause apnoea.			

and the neural–humoral responses to pain but are complicated by respiratory depression. Conversely, regional analgesia has been shown to be as effective as morphine infusions without causing sedation or ventilatory depression (Armitage 1988; Wolf and Hughes 1993), leading to faster recovery times. There are many recent studies to suggest that in experienced hands regional anaesthesia/analgesia is safe and easy with few side-effects (Strafford et al. 1995; Giaufre et al. 1996; Martinez-Telleria et al. 1997; Uguralp et al. 2002). Local anaesthetics can block nociceptive transmission at various sites – topically and by local infiltration to the skin, regionally by nerve blocks or neuroaxially via the caudal, lumbar or thoracic epidural route. Single-shot administration can provide up to 12 hours of analgesia or indwelling catheters can be used for local anaesthetic infusions or repeat bolus.

Newborns are at a higher risk for local anaesthetic toxicity, which had previously led to concern over the use of local anaesthetics in this age group. Lower alpha-1-glycoprotein levels (Lerman et al.

1989) and reduced clearance of amide local anaesthetics result in potentially higher plasma levels, which can cause seizures and cardiovascular collapse (Berde 1993). This is further exacerbated by acidosis, hypoxia, hypercapnia, hyponatraemia and hyperkalaemia – and the neonate is at a greater risk for developing many of these. Care should be taken when calculating the safe maximum doses of lidocaine (3 mg/kg) and bupivacaine (2 mg/kg bolus). Epidural infusions of bupivacaine (0.2 mg/kg/h, 1.25 mg/ml) can be given safely for up to 48 hours but Larsson et al. (1997) found a significant number of neonates had a still rising plasma bupivacaine level at 48 hours, suggesting that accumulation may occur with prolonged epidural infusions.

Eutectic mixture of local anaesthetics (EMLA) contains 2.5% lidocaine and 2.5% prilocaine. Prilocaine has a metabolite *o*-toluidine which can cause methaemoglobinaemia. Taddio et al. (1998), in a meta-analysis of 11 trials, showed the incidence of clinically relevant methaemoglobinaemia to be zero, allaying previous concerns over the use of EMLA in those under 3 months. However, the risk of

Table 25.4 A suggested plan for provision of analgesia in the neonatal unit for various common scenarios

Postoperative analgesia	
Non-ventilated baby	<ol style="list-style-type: none"> 1. Determine opioid history e.g. loading dose in theatre or long-term administration 2. Inadequate analgesia 10–50 µg/kg iv morphine* bolus over 15 minutes with formal pain/comfort scoring at 5-minute intervals until analgesia is optimal 3. Analgesia maintenance 0–20 µg/kg/h iv morphine* 4. Regular paracetamol (caution after 48 hours: see text) 5. Transfer to enteral analgesics, e.g. codeine, as soon as possible
Ventilated baby	<ol style="list-style-type: none"> 1. Inadequate analgesia 50–150 µg/kg iv morphine* bolus as required 2. Analgesia maintenance 0–40 µg/kg/h iv morphine* 3. Regular paracetamol (caution after 48 hours: see text) 4. Fentanyl* with critically ill babies (conveys haemodynamic stability) 0.5–10 µg/kg iv bolus if analgesia inadequate 2.5–10 µg/kg/h for iv maintenance
Background sedation	
Ventilated baby	<ol style="list-style-type: none"> 1. Opioid infusion Critically ill baby: use fentanyl* 2.5–10 µg/kg/h iv Otherwise morphine* 0–20 µg/kg/h 2. Optimise opioid infusion with pain/comfort scoring Limit dose to reduce tolerance (kinetic and dynamic) Ensure adequate analgesia to avoid stress response 3. Consider secondary agents to reduce opioid requirements Sedatives, e.g. triclofos or lorazepam Clonidine 4. Non-pharmacological strategies (see text)
Procedural analgesia	
e.g. venepuncture or chest drain insertion	<ol style="list-style-type: none"> 1. Use local anaesthesia where possible; first establish appropriate safe dose for patient then consider: Local infiltration EMLA (allow skin contact of at least 60 minutes) Ametop (allow skin contact of 45 minutes) 2. Non-pharmacological strategies (see text) 3. Consider single iv opioid bolus (as above)
<p>*Infants receiving opioid infusions must be fully monitored with regular formal pain/comfort scoring in a high-dependency or intensive care unit. EMLA, eutectic mixture of local anaesthetics.</p>	

significant methaemoglobinaemia increases if excess doses are used too frequently and if other methaemoglobin-inducers are used. Amethocaine is an alternative topical anaesthetic that is being increasingly used in the UK; further studies are needed to establish its safety for the newborn but early work suggests it to be a safe and effective anaesthetic for venepuncture after 40–60-minutes' application in newborn infants from 27 weeks' gestation and lasting 4–6 hours (Jain and Rutter 2000). Both EMLA and Ametop have been found to be not particularly effective for heel-lancing pain. Venepuncture by an experienced practitioner causes less pain than heel-lancing and should be the method of choice (Shah and Ohlsson 1999). Neonatal circumcision is still widely performed without anaesthesia and has been shown to have long-term effects on pain perception 6 months after the procedure (Taddio et al. 1997). In a Cochrane review EMLA was found to attenuate the physiological effects of pain following circumcision (Taddio et al. 2000). However the authors concluded that, while EMLA was more effective than placebo and should be used in place of nothing, there are more effective analgesic methods such as penile dorsal nerve blocks and ring blocks which need further evaluation – initial reports suggest dorsal nerve blocks to be safe with a low incidence of complications (Fontaine et al. 1994).

Environmental and behavioural interventions

There is a growing body of evidence that environmental, behavioural and non-pharmacological strategies can reduce the behavioural and physiological indicators of pain and stress in the newborn. These principles are encompassed in the concept of

developmental care which leads to improved neurobehavioural organisation, lower morbidity and earlier discharge (Als et al. 1986, 1994). Minimising painful procedures to those absolutely necessary and clustering them together can reduce the frequency of noxious stimuli. Other techniques thought to be beneficial include decreasing handling, reducing ambient noise and light, and establishing day–night cycles (Franck and Lawhon 1998).

Behavioural strategies useful in reducing pain scores during painful procedures include gentle sensory stimulation of the visual, tactile (Gray et al. 2000), auditory (Locsin 1981) and taste senses. Oral sucrose and sweet compounds are safe and effective at reducing pain scores during invasive procedures. There is a dose-dependent effect from 5% to 50% but the optimal dose is not known (Stevens and Ohlsson 2000). Bellieni et al. (2001) combined oral 10% glucose, non-nutritive sucking and multisensorial stimulation into a process of 'sensorial saturation'. They found that this was more effective at reducing pain scores than any of these techniques alone (Bellieni et al. 2001). A Cochrane review has recommended oral sucrose as analgesia for procedural pain in newborns, based on its effect in reducing pain scores (Stevens et al. 2010), but a recent randomised controlled trial has demonstrated that, while reducing the PIPP score, oral sucrose does not reduce the cortical response (Slater et al. 2010b). Proprioceptive, vestibular and thermal stimulation occurs through swaddling, rocking and maintaining a flexed position (facilitated tucking) (Franck and Lawhon 1998). The use of melatonin is still in the research domain but it may prove useful to regulate the circadian rhythm (Seron-Ferre et al. 2001). An overview of general strategy is shown in Table 25.4.

Introduction

Substance abuse in pregnancy poses serious health risks to mothers and the developing baby, as well as potentially hindering parents' ability to care adequately for their children. Babies can suffer from consequences of congenital malformations and the adverse effects of drugs on pregnancy, or develop acute drug withdrawal after birth.

Drug abuse is common in women of childbearing age: the European Monitoring Centre for Drugs and Drug Addiction annual report for 2008 ([EMCDDA 2008](#)) states that, in the 16–34-year age group in England and Wales, 13.8% of individuals have used cannabis, 4.5% cocaine, 3.1% ecstasy and 1.8% amphetamines during the preceding year. Rates are slightly higher for all drugs in Scotland and lower in Northern Ireland. Drug use is even higher in the 16–24-year age group and 0.2% of all adults surveyed in England and Wales admitted to opiate use in the preceding year. Accurate figures for fetal exposure to substance abuse are difficult to obtain because of the illegal status of most drugs of abuse. In pregnancy rates of abuse of 0.4–31% have been reported ([Khalsa and Gfroerer 1991](#)). Although drug abuse occurs in all races and social classes, there is an increased risk in women who are younger, unmarried or who have lower educational achievements. In the USA, the National Survey on Drug Use and Health of 2008 revealed 5.2% of pregnant women admitted using illicit drugs in the previous month; however underreporting is very likely ([Substance Abuse and Mental Health Services Administration 2008](#)).

A study of 3000 babies born in a high-risk obstetric population in the USA revealed 44% were positive for morphine, cocaine or cannabis using meconium immunoassay, although only 11% of mothers admitted using illegal drugs ([Ostrea et al. 1992](#)). A study of 30 000 maternal urine samples at delivery in 1992 in California showed 5% of samples contained one or more illicit drugs ([Vega et al. 1993](#)). Meconium analysis from 400 infants in a study in Glasgow in 2001 revealed that approximately 13% of samples were positive for cannabinoids, 2.75% for cocaine and 1.75% for amphetamines ([Williamson et al. 2006](#)). Testing of 807 consecutive positive pregnancy tests in an urban UK population revealed approximately 17% (one in six women) were positive for illegal substances: 14.5% for cannabinoids, 1.4% for opiates, 0.5% for benzodiazepines, 0.4%, ethanol 0.2% for cocaine, 0.1% for amphetamines and 0.1% for methadone ([Sherwood et al. 1999](#)).

General effects of substance abuse in pregnancy

Substance abuse during pregnancy can have adverse effects on the health of the mother, the pregnancy itself, the fetus and the newborn infant after birth. Poverty, poor nutrition and lack of antenatal care also independently have a detrimental effect on pregnancy outcome. There is also a high risk of acquiring human immunodeficiency virus (HIV), hepatitis B and hepatitis C infection with intravenous drug use. Intrauterine growth restriction and preterm birth are more common (Messinger et al. 2004).

The effects of substance abuse on the fetus can be divided into drugs that have a direct teratogenic effect during the first trimester of pregnancy (e.g. cocaine; see Table 26.1), those which influence ongoing fetal growth or development through continued exposure (e.g. alcohol and barbiturates) and those which can have an adverse effect in the neonatal period by causing sedation, fits or withdrawal (e.g. benzodiazepines or opioids).

Providing appropriate care to this group is often challenging. Flexible care from experienced multidisciplinary teams is required, with child safeguarding a priority.

Approach to management of substance abuse in pregnancy

If a mother is suspected of abusing drugs a careful history should be taken regarding the quantity, duration, frequency and route of drug use, and counselling and support should be offered, along

with multidisciplinary antenatal care. A careful search should be made for comorbid conditions such as psychiatric disorders, domestic violence, sexual or emotional abuse, the presence of sexually transmitted diseases and blood-borne virus infection (hepatitis B, hepatitis C and HIV infection). Frequent antenatal visits with serial ultrasound scans should be offered to confirm gestation and monitor fetal growth and well-being. If there has been high-risk behaviour such as sex-working or intravenous drug abuse continuing during the pregnancy, repeated virology testing is indicated (see Ch. 39.2).

The precise model of care will vary depending on local circumstances, but an example of a care pathway is given in Figure 26.1. A multidisciplinary open-access service may improve engagement by reducing the burden of appointments and improve continuity and consistency of care. Such a service might involve a specialist midwife, obstetrician, liaison health visitor, neonatologist, neonatal nurse and social worker. In general, the initial approach should be to deal with the elements of substance abuse that contribute the greatest risk to the mother and fetus, such as injecting or regular alcohol abuse. The aim is then to reduce chaotic drug use, eventually achieving a stable period without use of illegal drugs before considering detoxification. Moving to detoxification too quickly can increase the chances of relapse.

General management of infants of substance-abusing mothers

Assessment following birth should include careful physical examination for evidence of malformation (Tables 26.1 and 26.2). Further investigations may be indicated, such as cranial ultrasound and eye examination. Toxicology screening (see Methods of testing, below) should be considered, particularly if there was no toxicology monitoring in pregnancy. Assessment for signs of neonatal withdrawal – also called neonatal abstinence syndrome – should be made (see Assessment of withdrawal, below). The most common drugs likely to result in withdrawal are opioids, benzodiazepines, antidepressants and alcohol. The timing of onset of symptoms depends on the drug(s) taken (Table 26.3), and there may be more than one phase in polydrug abuse. The signs and symptoms of withdrawal from different drugs are broadly similar and largely non-specific with central nervous system irritability and autonomic system dysfunction. Opioids are more likely to cause significant autonomic dysfunction (Table 26.4) than substances such as cocaine, amphetamines or benzodiazepines that cause predominantly central nervous system symptoms (see Table 26.2) (Oei and Lui 2007). Differential diagnoses include hypoglycaemia, hypocalcaemia, hypomagnesaemia, hyperthyroidism and causes of neonatal encephalopathy, such as central nervous system haemorrhage, sepsis and hypoxia. Drugs that are associated with neonatal seizures include opioids, shorter acting barbiturates, tricyclic antidepressants, alcohol, selective serotonin reuptake inhibitors (SSRIs) and serotonin noradrenaline reuptake inhibitors (SNRIs).

Supportive therapy should be offered with minimal stimulation and with swaddling or skin-to-skin care, the use of a dummy and frequent feeding. If pharmacological therapy is required a drug from the same class as that which is causing withdrawal may be preferable where possible. There are few comparative studies of different drugs used in the treatment of withdrawal. The most commonly used treatments, their main components and their mechanism of action are outlined in Table 26.5. A survey of the management of withdrawal in the UK and Ireland (O'Grady et al. 2009) showed morphine sulphate was the most commonly used first-line agent for opiate withdrawal by 92% of units, and in polysubstance

Table 26.1 Maternal drugs associated with teratogenic effects

DRUG	MALFORMATION
Alcohol	Fetal alcohol spectrum disorder (Volpe 2008)
Anticonvulsants Barbiturates Phenobarbital*	Fetal hydantoin syndrome: abnormal pre- and postnatal growth, central nervous system function, craniofacial appearance and distal limbs Neural tube defects, cardiac anomalies, facial clefts, hypospadias, other genitourinary anomalies, gastrointestinal anomalies and skeletal defects (Holmes et al. 2001; Volpe 2008)
Cocaine	Central nervous system: microcephaly, agenesis of the corpus callosum or septum pellucidum, septo-optic dysplasia, lissencephaly and schizencephaly (Volpe 2008) Possible increase in urogenital anomalies (Chasnoff et al. 1988; Chávez et al. 1989)
Selective serotonin reuptake inhibitors	Increased risk of septal heart defects with first-trimester use of sertraline and citalopram (Pedersen et al. 2009)

*Teratogenic effects are more common with multiple anticonvulsant therapy in pregnant women.

Fig. 26.1 Model care plan.

Table 26.2 Effects of cocaine on the fetus and newborn

OBSERVATION	PUTATIVE MECHANISMS
Uterine stimulation	Catecholamines
Placental abruption	Direct effect on myometrium
Preterm birth	
Fetal hypoxia, death	Catecholamine-induced vasoconstriction of maternofetal unit
Intrauterine growth retardation: reduced weight, length and head circumference	Increased fetal metabolic rate
Central nervous system malformation (see Table 26.1)	Direct effect on neuronal migration and differentiation
Intraventricular haemorrhage/infarction	Disturbed autoregulation/hypertensive episodes/vasoconstriction
Meconium-stained liquor	Sympathetic activation
Necrotising enterocolitis	Sympathetic activation
Limb reduction defects	Vasoconstrictive episodes
Retinal infarction	Vasoconstrictive episodes
Gut atresias	Vasoconstrictive episodes
Myocardial ischaemia	
Genitourinary anomalies	
Increased sudden infant death syndrome	Secondary to abnormal sleep patterns and arousal

Table 26.3 Drugs described as being associated with neonatal withdrawal

DRUG	TIME OF ONSET OF WITHDRAWAL
Opiates/opioids	
Heroin	0–48 hours, peak 12–24 hours
Methadone	1–5 days, peak 2–3 days
Codeine	<48 hours
Dihydrocodeine (DF118)	<48 hours
Oxycodone (Percocet/OxyContin)	<24 hours
Pentazocine	<24 hours
Alcohol	<24 hours
Benzodiazepines	
Diazepam (Valium)	2–6 weeks
Chlordiazepoxide (Librium)	3 weeks
Tricyclic antidepressants	0–72 hours
SSRIs/SNRIs	0–72 hours
Cocaine*	48–72 hours
Barbiturates	
Shorter acting	0–24 hours
Long acting	2–4 months
Amphetamines	–
Phencyclidine hydrochloride (PCP/angel dust)	24–72 hours
<p>*Direct effect of the drug, not withdrawal. SSRIs, selective serotonin reuptake inhibitors; SNRIs, serotonin noradrenaline reuptake inhibitors.</p>	

Table 26.4 Signs of opiate withdrawal

CENTRAL NERVOUS SYSTEM	GASTROINTESTINAL	AUTONOMIC AND OTHER
Tremors Irritability High-pitched cry Hypertonicity Hyperactivity Increased wakefulness Excess sucking Poor feeding Exaggerated Moro reflex Seizures	Poor feeding Uncoordinated suck Vomiting Diarrhoea Dehydration	Yawning Sweating Fever Hiccups Tachypnoea Fever/temperature instability Poor weight gain Excoriation of skin due to rubbing Skin mottling Nasal congestion Salivation

Table 26.5 Agents used for treating neonatal withdrawal

DRUG	MAIN COMPONENTS/MECHANISM OF ACTION/INDICATIONS FOR USE	DOSE
Opiates		
Morphine	Opiate replacement Opiate/opioid withdrawal Treatment of withdrawal seizures	50–100 µg/kg 6-hourly increasing by 25–50% every 24–48 hours until symptoms are controlled.
Methadone	Opiate replacement Opiate/opioid withdrawal Treatment of withdrawal seizures	Can be increased to 4-hourly (Osbourne et al. 2005) Methadone 100 µg/kg 6-hourly increased by 50 µg/kg until symptoms controlled (British National Formulary for Children 2010–2011)
Tincture of opium* Paregoric†	Opiate replacement Opiate/opioid withdrawal Treatment of withdrawal seizures	
Chlorpromazine	A phenothiazine antipsychotic which can cause sedation, reduce seizure threshold and cause cerebellar dysfunction Controls CNS and gastrointestinal signs of opiate/opioid withdrawal (Kahn et al. 1969). High risk of seizures if used as sole agent in opioid withdrawal May be useful in the treatment of SSRI withdrawal (Nordeng et al. 2001) and in benzodiazepine withdrawal	0.5–1 mg/kg every 6 hours intramuscularly or orally (maximum 6 mg/kg daily). When stable wean dose by maximum 2 mg/kg daily every third day
Phenobarbital	A barbiturate anticonvulsant. Sedative Long half-life: monitor blood levels Most commonly used treatment for opiate/opioid withdrawal seizures May be a useful second-line treatment of opioid withdrawal but does not alleviate gastrointestinal symptoms; however reduces duration of care needed (Osborn et al. 2005) Reported to be effective in withdrawal from volatile inhalant substance abuse (Tenenbein et al. 1996)	Loading dose 20 mg/kg intravenously then maintenance 2.5–5 mg/kg once daily intravenously or orally. (Check trough levels: aim for 20–40 mcg/ml)
Diazepam	A benzodiazepine Widely used in adults to control symptoms of alcohol withdrawal Replacement in benzodiazepine withdrawal As an anticonvulsant	For seizures 1.25–2.5 mg per rectum 300–400 µg/kg intravenously
Clonidine	A non-narcotic alpha 2 stimulant which decreases symptoms of withdrawal in opiate-addicted adults and children (Gold et al. 1978; Baumgartner and Rowen 1991) May be useful adjunct therapy to decrease hypertension and tachycardia in alcohol withdrawal Reduces duration of drug treatment in opioid withdrawal when used with opiate replacement (Agthe et al. 2009) 6 out of 7 infants with opiate withdrawal treated successfully with clonidine (Hoder et al. 1984)	3–5 µg/kg/day, divided into 4–8-hourly doses (test dose–1mcg/kg watch for hypotension)
*Tincture of opium (used in the USA but not widely used in the UK) (Anonymous 1998). †Paregoric, a mixture of opium, camphor, alcohol and anise oil, is no longer in use due to toxicity of additives. CNS, central nervous system; SSRIs, selective serotonin reuptake inhibitors.		

withdrawal by 69% of units. Phenobarbital was the first choice for treatment of seizures from opiate withdrawal and polydrug withdrawal in 73% and 81% of units respectively. A similar survey in the USA revealed that 63% of neonatal units used opioids (either tincture of opium or morphine sulphate) to treat opioid withdrawal and 52% used opioids to treat polydrug withdrawal. In the USA, 70% of units used phenobarbital and 25% used morphine to control opioid seizures; 81% used phenobarbital to control seizures secondary to polydrug withdrawal (Sarkar and Donn 2006).

Urgent infant HIV and hepatitis B testing is indicated at birth if mothers are untested or there has been continuing high-risk

behaviour since previous tests to enable commencement of appropriate treatment to reduce the possibility of perinatal viral transmission. Consideration should also be given to routine hepatitis B immunisation.

Methods of testing

Urinalysis is the most commonly used method to detect and monitor substance abuse in the mother and newborn infant. Intermittent drug use can be missed as many drugs of abuse are present in the blood and urine for just a few hours (with the notable

exception of marijuana, with which the urine can remain positive for weeks). Rapid urine dipstick testing is available, but full laboratory analysis can give more information on persisting drug metabolites. Mouth swabbing of mothers can detect recent use of many illicit substances, but is more likely to produce false-negative results than urine testing. Breathalyser testing is easy to perform and useful where there have been problems with alcohol abuse. Maternal or infant hair, meconium (Ostrea et al. 2001) and homogenised cord tissue testing (Montgomery et al. 2006) reflect historical drug use several months prior to delivery, but are not routinely available.

Assessment of withdrawal

A variety of scoring charts for monitoring symptoms of neonatal withdrawal are in use. The modified Finnegan chart is the most widely used (Fig. 26.2) – by 52% of units in the UK and 65% of neonatal units in the USA (Finnegan et al. 1975; Lipsitz 1975).

There are a number of problems with using this scoring system in clinical practice. These include an overemphasis on minor symptoms, interobserver variability and a tendency to 'score' infants at the time the chart is completed rather than reflecting the status of a baby over the preceding hours. In addition, the scoring for length of sleep following a feed is less appropriate for babies who are in the early stages of establishing breastfeeding than it is for those who are bottle-feeding. A total derived from the scoring chart is often used as a threshold for commencing pharmacological treatment, and will vary depending upon the type of scoring system used. A modified Finnegan score of ≥ 8 on two consecutive assessments 4 hours apart is a commonly used threshold for treatment. Scoring can help to assess changes over time but it should not replace the use of clinical judgement. The key indications for treatment are significant feeding problems (including vomiting and need for nasogastric feeding), watery diarrhoea or the baby remaining very unsettled despite feeds, swaddling and the use of a dummy.

Breastfeeding

The benefits of breastfeeding mean that it should be encouraged whenever it is safe to do so. However, many drugs of abuse such as heroin, amphetamine, cocaine and phencyclidine pass readily into breast milk and breastfeeding is not advised if the mother continues to abuse these substances or is HIV-positive. Methadone by contrast is highly protein-bound in maternal plasma; therefore, only very small amounts pass into breast milk, but this is poorly correlated with maternal dose. There is now a growing amount of evidence to support its safe use in women who are breastfeeding (Philipp et al. 2003). Breastfeeding with the abuse of any drug depends upon a careful assessment of the risks and benefits. For example, breastfeeding with low doses of maternal diazepam could be considered if the baby is monitored for any evidence of the potential consequences of sedation such as difficulty sucking or poor weight gain.

Outcome

When examining pregnancy outcome it is difficult to prove a causal relationship between drug abuse in pregnancy and adverse outcome. This is because of the difficulties in controlling for pregnancy complications, poor maternal health and social circumstances, maternal malnutrition, poverty and maternal chronic infections such as HIV or hepatitis B or C. Low birthweight and prematurity, which are also more common, themselves contribute to increased risk of poor outcome. Unrecognised or untreated withdrawal can cause

significant morbidity and mortality in the newborn. There are also reports of increased risk of sudden infant death syndrome in infants of opioid-abusing mothers (Hunt and Hauck 2006). The largest longitudinal cohort study ($n = 1227$) looking at outcome with cocaine and opiate exposure found that, after controlling for birthweight and environmental risks, there was no association with developmental, motor or behavioural deficits (Messinger et al. 2004).

Specific drugs of abuse

Opiates/opioids

Opioids are natural and synthetic substances with morphine-like activity. Opiates are a subclass of opioids extracted from opium, including morphine, codeine, heroin and methadone. Heroin still accounts for the greatest share of morbidity and mortality related to drug use in the European Union. However in the last decade its use may have declined slightly in favour of synthetic opioids such as fentanyl (EMCDDA 2009). Between 1 and 6 per 1000 15–64-year-olds in Europe have a significant opiate addiction (EMCDDA 2009). Continued abuse of illegal opioids during pregnancy increases the risks of miscarriage, premature delivery and low birthweight, and the risk of blood-borne infections is high for those who inject (Lam et al. 1992). Sudden cessation of a regular drug habit can result in pregnancy loss and therefore mothers should seek specialist advice before discontinuing their drug use abruptly. Methadone replacement therapy can be used to manage opioid abuse safely in pregnancy (Jones et al. 2008) and there is no evidence of an increase in fetal malformations. Appropriate doses of methadone eliminate the pharmacological symptoms of withdrawal in the mother. This can lead to a reduction or cessation in illegal opioid abuse that reduces the ongoing risks to the mother and fetus, increasing the chance of a favourable outcome. More recently, other types of opioid substitution treatment are being used, in particular buprenorphine (Jones et al. 2008), the use of which may increase as the subsequent neonatal withdrawal is shorter than that of methadone.

The risk of withdrawal is greatest with heavy opiate abuse in the 3 months prior to delivery. Naloxone should be avoided at resuscitation because of the high risk of precipitating acute withdrawal. Withdrawal from methadone varies depending on dose (<20 mg/day, 10%; 20–40 mg/day, 40–50%; 60 mg/day or greater, 90%) (Dashe et al. 2002). Preterm infants <35 weeks seem to manifest less severe symptoms than term infants (Doberczak et al. 1991), which may be secondary to developmental immaturity of the central nervous system or less prolonged fetal exposure. Most opiates (see Table 26.3) have short half-lives and therefore cause withdrawal symptoms within 48 hours of delivery. Methadone, which has a longer half-life, causes a more gradual onset of symptoms and infants usually present around 2–3 days of age. Presentation of withdrawal after 5 days is very unlikely (Shaw and McIvor 1994); however if withdrawal symptoms are already present these can increase and worsen over the first 10 days as methadone is excreted by the baby and the proportion of occupied opiate receptors decreases. This explains why the dose of medication required to treat opiate withdrawal sometimes needs to be increased during this period. Withdrawal from opioids is characterised by marked central nervous system symptoms and autonomic disturbance with gastrointestinal upset (see Table 26.4). Significant withdrawal (see Assessment of withdrawal, above) not responding to supportive care will require drug treatment (see Table 26.5). The treatment of choice is morphine sulphate (Osbourne et al. 2005), although other opiate-based treatments have been used successfully,

	SYMPTOMS		SCORE		
CNS	Excessive high-pitched cry <5 mins	2			
	Continuous high-pitched cry >5 mins	3			
	Sleeps <1 hour after feeding	3			
	Sleeps <2 hours after feeding	2			
	Sleeps <3 hours after feeding	1

Fig. 26.2 Modified Finnegan chart. (Modified from Finnegan LP, Connaughton JF Jr, Kron RE, Emich JP. Neonatal abstinence syndrome: assessment and management. *Addict Dis.* 1975;2(1-2):141-58.)

particularly in the USA. Morphine is widely available and has a short half-life that achieves stable drug levels and symptom control relatively quickly. Treatment should be aimed at normalisation of infant behaviour without oversedation. Cardiorespiratory monitoring is recommended until this is achieved.

Adjunct therapy with clonidine reduces the duration of drug treatment in opioid withdrawal when used with opiate replacement. Phenobarbital may also be useful in reducing the duration of care needed but does not alleviate gastrointestinal symptoms. If seizures are present despite opiate treatment, the usual anticonvulsants are indicated (diazepam, clonazepam, phenobarbital). Phenobarbital is the anticonvulsant most commonly used for withdrawal in the UK and USA (Sarkar and Donn 2006; O'Grady et al. 2009).

Control of opioid withdrawal is usually possible by 10–14 days. After stability is achieved for at least 48 hours, a reduction of morphine can be commenced either in hospital or in the community when the parents or carers feel confident to assess their baby and administer the medication. Reduction should be in 10% increments or less at intervals of 2–3 days or more according to initial response. The relationship between opioid exposure in pregnancy and neurodevelopmental outcome is inconsistent because of difficulty in controlling for confounding variables such as low birthweight, prematurity, multiple drug exposure and quality of home environment. Severity of withdrawal has not been shown to alter the long-term outcome (Messinger et al. 2004).

Cocaine

Cocaine abuse in pregnancy is a major concern. Infant meconium and early pregnancy maternal urine testing in the UK suggests that approximately 3% of pregnant women use cocaine whilst pregnant. Cocaine can be taken by inhalation of the powder or by intravenous injection. Other derivatives such as its freebase (crack) can be smoked (often mixed with cannabis or tobacco). Cocaine creates prolonged sympathetic nervous stimulation, causing vasoconstriction and hypertension. It freely crosses the placenta and fetal blood–brain barrier. Vasoconstriction is the main mechanism for fetal damage. Exposure to cocaine in pregnancy is associated with clear drug-induced effects (Table 26.2) (Plessinger and Woods 1993; Ogunyemi and Hernández-Loera 2004; Bauer et al. 2005). Higher early-pregnancy loss and third-trimester complications and an increased risk of stillbirth, sudden infant death syndrome and neonatal death are more common with cocaine abuse in pregnancy. Teratogenic effects on the central nervous system are well recognised secondary to the effect of cocaine on neuronal migration and differentiation (see Table 26.1) (Volpe 2008). Other teratogenic effects of cocaine have not been definitively established but there is likely to be an increase in urogenital anomalies (Chasnoff et al. 1988; Chávez et al. 1989). Cardiovascular toxicity in women causes hypertension, which can mimic the effects of pre-eclampsia. Exposure in utero to cocaine may lead to fetal cerebral infarction, intracranial haemorrhage or retinal vascular damage (McGlone et al. 2009).

Cocaine abuse close to the time of delivery may present between 48 and 72 hours of age with tremor, hypertonia, high-pitched cry, irritability, excess suck, hyperalertness and tachycardia; these are thought to be the direct effect of cocaine rather than of withdrawal (Anonymous 1998).

Deficits have been found in neurobehavioural features such as attention, emotional control, aggressiveness and emotional expressivity and in higher motor functions, which can be ameliorated by a high-quality home environment (Singer et al. 2004; Volpe 2008). Supportive therapy is usually sufficient for withdrawal symptoms.

Careful examination for congenital anomaly, including cranial ultrasound and ophthalmological review, should be undertaken. Breastfeeding should be avoided with cocaine use as it transfers readily to breast milk and there have been reports of seizures following breastfeeding (Chasnoff et al. 1987).

Alcohol

'Fetal alcohol spectrum disorder (FASD) is an umbrella term used to describe a continuum of alcohol-related disorders, with fetal alcohol syndrome (FAS) the most severe form. At the other end of the continuum, the neurological and behavioural features of FASD may occur later without apparent dysmorphic features. A safe level of alcohol use in pregnancy has not been established. FAS is the most common identifiable cause of mental retardation in the world, with prevalence rates of 0.18–1.5 per 1000 live births (National Task Force on Fetal Alcohol Syndrome and Fetal Alcohol Effect 2004; Elliott et al. 2008). The prevalence of FASD is unknown, but is possibly as high as 1% of all live births in the USA (Sampson et al. 1997).

The diagnosis of FAS requires a history of alcohol ingestion associated with abnormal growth, neurological abnormality and the characteristic facial findings (short palpable fissures, smooth philtrum and thin vermilion border of the upper lip), as illustrated in Figure 26.3. Numerous additional features can occur and may add weight to the diagnosis, including feeding difficulties, mandibular hypoplasia, abnormal palmar creases, abnormal ear creases, nail hypoplasia, clinodactyly, cardiac defects, poor hearing and optic disc hypoplasia. Poor growth may manifest itself in antenatal and postnatal periods (<10th centile). Neurological abnormalities may be structural or functional and include microcephaly, structural brain abnormalities (in the corpus callosum, brainstem or basal ganglia) or seizures. Charts of lip and philtrum appearances such

Fig. 26.3 Child with fetal alcohol syndrome. (Courtesy of Professor Susan Astley.)

as that shown in Figure 26.4 offer a systematic approach to aid facial diagnosis (National Task Force on Fetal Alcohol Syndrome and Fetal Alcohol Effect 2004; Astley 2006). Careful clinical postnatal assessment for features of FASD should include an early cranial ultrasound and a low threshold for ophthalmological referral. Functional deficits may not be apparent in the neonatal period and follow-up is required by child health services if there is significant alcohol exposure during pregnancy. Following birth, infants exposed to alcohol can suffer acute withdrawal associated with hypoglycaemia and acidosis. Acute withdrawal usually only requires supportive measures with frequent small feeds. If seizures are present benzodiazepines or phenobarbital are the treatments of choice.

Prevention of FASD is the aim. Short screening questionnaires to identify alcohol abuse have been validated (Reinert and Allen 2007) and consideration should be given to their routine use at pregnancy booking to allow effective intervention.

Selective serotonin reuptake inhibitors/ serotonin noradrenaline reuptake inhibitors

Although SSRIs and SNRIs are not recreational drugs, they are widely used antidepressants which are known to cause significant symptoms in the newborn infants of mothers who take them in the third trimester of pregnancy. Depression and anxiety are common in pregnant women and SSRIs (e.g. fluoxetine, sertraline, citalopram and paroxetine) and SNRIs (e.g. venlafaxine, duloxetine) have been used increasingly during pregnancy and breastfeeding. It is likely that SSRIs and SNRIs only represent a very low risk of teratogenicity even if used in the first trimester. Fluoxetine, sertraline and paroxetine use in the third trimester carries an increased risk of low birthweight and growth restriction (Oberlander et al. 2006). Infants who are exposed to third-trimester SSRIs or SNRIs may suffer withdrawal, with predominantly central nervous system symptoms (Moses-Kolko et al. 2005; Nordeng and Spigset 2005; Sanz et al. 2005). Up to 60% of infants may show symptoms within 24 hours of birth which usually resolve spontaneously within a few days and are rarely serious, although seizures have been reported (Ferreira et al. 2007). There is an increased risk of developing persistent pulmonary hypertension of the newborn with paroxetine, sertraline or fluoxetine (Chambers et al. 2006). Chlorpromazine has been reported to be effective for symptom relief (Nordeng et al. 2001).

Other drugs of abuse

Marijuana

Marijuana is detectable in the neonatal urine days to weeks after exposure. It is the most commonly abused illicit substance. The impact of prenatal abuse on outcome is not clear. There is no evidence to support birth defects or increased mortality in the first 2 years of life in exposed infants (Ostrea et al. 1997). There may however be later effects on functioning, which may include cognitive defects, impulsivity, hyperactivity, depressive symptoms and substance use disorders (Gray et al. 2005; Huizink and Mulder 2006).

Cigarette smoking

Cigarette smoking in pregnancy has been associated with placental abruption, premature rupture of the membranes, placenta praevia, prematurity, low birthweight and increased early and late neonatal mortality (Cnattingius et al. 1988; Malloy et al. 1988; Mitchell et al.

Fig. 26.4 Lip-philtrum guide for fetal alcohol syndrome. (Reproduced from <http://depts.washington.edu/fasdpn/htmls/fas-face.htm>: accessed 22 June 2010.)

1997). There is a 2–4 times increased risk in sudden infant death syndrome in infants of mothers who smoke compared with infants of non-smoking mothers. Asthma is more common in children of mothers who smoked in pregnancy (Jouni et al. 2004).

Benzodiazepines

Benzodiazepines can be legally prescribed or abused. Higher doses in the last trimester can cause sedation, floppiness, apnoea, poor feeding and reduced weight gain in the early neonatal period secondary to the direct effect of the drug and metabolites. The onset of benzodiazepine withdrawal is often delayed, appearing slowly 1–4 weeks after delivery. Chlorpromazine can be effective in treating the symptoms but replacement therapy with a benzodiazepine (see Table 26.5) may also be considered: this then requires a staged reduction. No long-term detrimental effect on neurodevelopmental outcome has been shown (McElhatton 1994).

Amphetamines

Methamphetamine (speed, meth, ice, crystal) is a very addictive stimulant. It is estimated that 5% of pregnant women in the US population have used it during their pregnancy (Arria et al. 2006). Prenatal amphetamine exposure is likely to be associated with prematurity (Oei et al. 2010) and intrauterine growth restriction, although study confounders such as multiple drug use prevent a definitive conclusion (NTP-CERHR 2005; Smith et al. 2006). It remains uncertain whether there is an increased risk of congenital anomaly or negative impact on neurodevelopmental outcome.

Phencyclidine hydrochloride (PCP/angel dust)

There is limited evidence from small studies, which show hyper-tonicity, irritability, sleep problems and temperature instability in newborns with prenatal exposure (Chasnoff et al. 1983; Golden et al. 1987; Wachsmann et al. 1989).

Barbiturates

These freely cross the placenta and are known teratogenic agents (see Table 26.1) which can cause acute or delayed withdrawal. Delayed withdrawal presents between 2 and 4 months. Treatment is usually supportive, but phenobarbital replacements may be indicated (see Table 26.5), and these require staged withdrawal.

3,4-methylenedioxymethamphetamine (MDMA), ecstasy

There are conflicting studies on the teratogenic effects of ecstasy, which include increased risk of talipes and congenital heart disease, but small patient numbers cannot confirm a causal relationship (McElhatton et al. 1999). Withdrawal is recognised in adults and paediatricians should be aware of a possible neonatal counterpart.

Inhalants

These are volatile compounds (hydrocarbons or nitrites) which produce effects of intoxication via direct inhalation. Abuse in pregnancy may increase the risk of miscarriage, prematurity or fetal malformation (Jones and Balster 1998). There is an association with cardiac arrhythmia and sudden death. Infants exposed in pregnancy may show symptoms of withdrawal after delivery. Phenobarbital has been used to control symptoms (see Table 26.5) (Tenenbein et al. 1996).

Ketamine

Ketamine is an anaesthetic induction agent which has a recognised withdrawal syndrome in adults characterised by poor attention span and restlessness. Similar symptoms may be possible in the neonatal period secondary to maternal abuse.

Tricyclic antidepressants

Tricyclic antidepressants are commonly prescribed antidepressants rather than drugs of abuse but infants can suffer withdrawal (including seizures) in the neonatal period within the first 72 hours following delivery. There is no evidence of increased congenital malformations or long-term adverse effects on development outcome (Simon et al. 2002).

Polydrug use

Polydrug use is common and it is often difficult to separate out the effects of individual drugs. Timing of withdrawal depends on which drugs are involved (Table 26.3). New symptoms developing in the second week of life are unlikely to be related to opioid withdrawal and other causes should be sought (e.g. benzodiazepines). It is difficult to make clear recommendations regarding drug treatment. Morphine sulphate or tincture of opium is the most commonly used treatment in the UK and USA for polydrug withdrawal (Sarkar and Donn 2006; O'Grady et al. 2009); however more than one drug may be required.

Summary

Substance abuse is common in women of childbearing age. Infants of substance-abusing mothers are at significant risk from the teratogenic effects of the drug, are more likely to suffer from preterm birth and growth restriction and are at risk of neonatal withdrawal. They also suffer significant social disadvantage if drug-seeking behaviour continues after delivery and interferes with normal parenting. Untreated or unrecognised withdrawal has significant morbidity and mortality. A multidisciplinary approach to mothers combined with careful antenatal planning and postnatal management can reduce the risk of harm and improve the outcome for mothers and their newborn infants.

Part 1: Physiology

Anne Greenough Anthony D Milner

Introduction

This chapter reviews the growth of the respiratory system before and after birth, the mechanisms responsible for the production and clearance of lung fluid, how the healthy infant achieves an expanded air-filled lung, the fetal and postnatal development of respiratory control and the development and function of surfactant and the surfactant proteins.

Morphological development of the lung

The primary goal of lung development is to create a large gas exchange area with a thin air–blood barrier. This is achieved by branching of the airways to form the conducting and proximal respiratory airways and by septation to subdivide the airspaces into alveoli (Roth-Kleiner and Post 2005).

There are four major stages of lung development:

1. 3–6 weeks
2. 6–17 weeks: pseudoglandular
3. 17–26 weeks: canalicular
4. 27 weeks to term: alveolar.

The nerves of the lung develop from neural crest cells and migrate via the vagus nerve to the future trachea and lung; there is then progressive extension of the nerve supply (Sparrow et al. 1999). The human fetal lung originates in the 3-week-old embryo as a ventral diverticulum that arises from the caudal end of the laryngotracheal groove of the foregut. The commitment of the foregut endoderm cell to form the lung bud is dependent on the transcription factor, hepatocyte nuclear factor 3-beta (Ang and Rossan 1994). The lung primordium divides into the right and left lung buds and then there is a repetitive process of invasion of the new buds into the surrounding mesenchyme, formation and elongation of the airway tubes and their division to form new airway buds (Roth-Kleiner and Post 2005). Fibroblast growth factor-10 (FGF-10)-stimulated sonic hedgehog (Shh) production in the epithelium of the lung bud and increasing expression of Shh and bone morphogenetic protein 4 (BMP4) lateralises FGF-10 activity, which induces outgrowth of new end buds (Roth-Kleiner and Post 2005). The bronchial tree is developed by the 16th week of gestation. Gli proteins are essential for lung-branching morphogenesis (Motoyama et al. 1998). During the canalicular stage of development, there is continued branching of respiratory bronchioles, vascularisation of the terminal tubules and thinning of the airway epithelium. Arteries and veins develop alongside the respiratory airways. Towards the

end of the canalicular stage (24 weeks), pulmonary gas exchange becomes theoretically possible. By 20–22 weeks of gestation, both type I and type II pneumocytes can be identified. Type I cells are flattened and form over 90% of the gas-exchanging surface of the mature lung. The cuboidal type II cells have a secretory function, and, from 24 weeks, osmiophilic lamellar bodies containing surfactant can be identified.

From 24 weeks to term, further terminal branching occurs, with the development of saccules. New tissue ridges are lifted off the existing primary septa and grow in a centripetal direction into the airspaces. These secondary septa subdivide the sacculi into smaller units, the alveoli (Roth-Kleiner and Post 2005). During this period, a capillary network forms around each saccule. A variety of growth factors and their receptors as well as extracellular matrix proteins are involved in the angiogenic process and may also be involved in branching and septation (Table 27.1) (Roth-Kleiner and Post 2005). For example, vascular endothelial growth factor (VEGF- α) is expressed by respiratory epithelial cells, stimulating pulmonary vasculogenesis mediated via paracrine signalling to receptors expressed by progenitor cells in the mesenchyme (Whitsett and Wert 2006); inhibition of VEGF signalling using a blocker Su-5416, either before or after birth, resulted in reduced vascularisation and alveolarisation (Le Cras et al. 2002).

Although alveoli begin to appear as shallow indentations at about 32 weeks of gestation, most alveolar development occurs postterm. The lung grows postnatally mainly by an increase in alveolar number, and, by 4 years of age, the adult number of alveoli is present (Thurlbeck 1982). The subsequent increase in lung volume and surface area is due to an increase in alveolar size. In the first 5 years, there is little elastin in the alveolar walls, which only extends around the alveolar walls by 18 years (Loosli and Potter 1959); the early 'relative' deficiency of elastin may facilitate the increase in size of the alveoli in the growing lung. There is a two- to threefold increase in diameter and length of airways between birth and adulthood (Hislop and Haworth 1989). The amount of bronchial smooth muscle relative to airway size increases between birth and adulthood; the increase in the first weeks after birth is particularly rapid.

Factors influencing lung growth and development

Abnormal lung growth can be the result of inadequate space, or reduction in either fetal breathing or amniotic fluid volume. The time of onset of the insult determines which structures are affected.

Table 27.1 Effect of growth factor activity on branching and septation

	BRANCHING	SEPTATION
FGF-7	↓ Branching	
FGF-10	↓ Branching	
FGF-3/FGF-4	–	↓ Alveolarisation
Shh	↓ Branching	
PDGF-A	↓ Branching	↓ Alveolarisation
PDGF-B	Branching normal but ↓ lung growth	
VEGF	↓ Branching	↓ Alveolarisation
TGF-β	↑ Branching	Emphysema in adults
Bmp-4	Mice die before branching	
EGF/TGF-α	↓ Branching	
Wnt2	–	↓ Alveolarisation
Wnt5a	↑ Branching	
Wnt7b	↓ Branching	

Modified from Roth-Kleiner and Post (2005).
 FGF, fibroblast growth factor; Shh, sonic hedgehog; PDGF, platelet-derived growth factor; VEGF, vascular endothelial growth factor; TGF, transforming growth factor; Bmp, bone morphogenetic protein; EGF, epidermal growth factor; Wnt, signalling pathway which describes a network of proteins.

Prior to 16 weeks of gestation, branching of the airways is impaired permanently, which will also reduce the potential for the number of alveoli. An insult occurring later affects the number of alveoli. Space restriction can be due to an abnormality extrinsic to the lung, for example congenital diaphragmatic hernia, pleural effusion or asphyxiating thoracic dystrophy, or intrinsic to the lung, for example cystic adenomatoid malformation. Other factors influencing lung growth and development include malnutrition, particularly vitamin A deficiency (Massaro and Massaro 1996, 2000), maternal smoking (Milner et al. 1999) and glucocorticoid administration (Burri and Hislop 1998).

Fetal breathing movements

Phrenic nerve or cervical cord resections which abolish fetal breathing movements (FBMs) are associated with arrest of lung growth. Fetal breathing is dependent on normal diaphragmatic function and pulmonary hypoplasia in newborns occurs with generalised neuromuscular disorders, isolated phrenic nerve agenesis and diaphragmatic amyoplasia. During periods of FBM, rhythmical contractions of the diaphragm slow the loss of lung liquid and help to maintain lung expansion when the upper airway resistance is reduced; this may be the mechanism by which FBMs preserve lung growth.

Fetal lung liquid

In fetal life, work in animal models has demonstrated that the lung is filled with liquid, increasing from 4–6 ml/kg bodyweight at

Fig. 27.1 Schematic model to explain the secretory and absorptive states of the lung. Na^+/K^+ -ATPase (K^{Na}) generates a gradient for Na^+ which enters the intracellular space across the basolateral membrane linked to Cl^- (Cl^-). β (II) receptor; (Na , X) sodium channel in apical membrane; cAMP, cyclic AMP. (Reproduced from Walters & Ramsden (1985).)

midgestation to about 20 ml/kg near term. The hourly rate of production is initially 2 ml/kg, increasing to 5 ml/kg at term. Fetal lung liquid contributes one-third to one-half to the daily turnover of amniotic fluid. Compared with either amniotic fluid or plasma, lung liquid has a high chloride but low bicarbonate and protein concentration. The dominant force mediating lung liquid secretion is the secondary active transport of chloride ions from the interstitial space into the lung lumen (Fig. 27.1) (Olver and Strang 1974). Sodium ions and water follow passively down electrical and osmotic gradients. A pressure in the lumen of the lung approximately 1 cmH₂O greater than that in the amniotic cavity is generated, which is essential for lung growth. The presence of lung liquid is important for normal lung development; chronic drainage results in pulmonary hypoplasia (Fewell et al. 1983), and lung fluid restriction in the embryonic rat lung affects growth but not airway branching (Souza et al. 1995). Tracheal ligation increases fetal intrathoracic pressure and causes lung hyperplasia; experimentally this can reverse the pulmonary hypoplasia associated with oligohydramnios and congenital diaphragmatic hernia (DiFiore and Wilson 1994; Harrison et al. 1996). There is, however, concern that although tracheal ligation results in increased cell proliferation and normal-sized lungs, it may be associated with decreased surfactant production (Bullard et al. 1997) and altered alveolar structure (Davey et al. 2001).

During labour and delivery, the concentration of adrenaline (epinephrine) increases and, as a consequence, lung liquid secretion ceases and resorption begins. Fetal lung liquid absorption is

via activation or opening of sodium channels on the apical surface of the pulmonary epithelium (Hummler et al. 1996). Thyroid hormone and cortisol are necessary for maturation of the normal response of the fetal lung to adrenaline (Barker et al. 1991). Exposure to postnatal oxygen tensions increases sodium transport across the pulmonary epithelium (Ramming et al. 2000).

Amniotic fluid volume

Pulmonary hypoplasia is associated with oligohydramnios following prolonged rupture of the membranes or chronic drainage following amniocentesis. It appears to be due to the increased efflux of lung liquid from the intrapulmonary space and not the result of external compression of the fetal thorax squeezing out lung liquid, as the amniotic fluid pressure under such circumstances is at or below the normal range (Nicolini et al. 1989). Prolonged oligohydramnios is associated with a decrease in lung liquid volume and a reduction in both the rate of lung liquid secretion and tracheal fluid flow rate (Dickinson and Harding 1987).

Pulmonary circulation

The pulmonary blood vessels and lymphatics develop from the mesenchyme of the splanchnic mesoderm of the foregut; this surrounds the lung buds as they push out from the laryngeal floor. Adjacent blood vessels fuse to form a rudimentary vasculature. The vascular plexus within each lung bud becomes supported by paired segmental arteries, which arise from the dorsal aorta. At 32 days of gestation, the sixth branchial arches appear, which give off the pulmonary arteries, hence the segmental arteries cease to supply the lung. By 50 days of fetal age, the adult blood supply pattern is achieved. Occasionally, an early segmental artery persists, captured within a lobe or lung segment (see sequestered lobe, p. 587) (Haworth 1992). There is progressive dichotomous branching of the pulmonary arteries during lung growth; 70% of the preacinar arteries are formed between the 10th and 14th week of gestation. Additional branching in the canalicular phase and in the last trimester around the developing sacculi greatly increases the vascular supply to the area of gas exchange.

During fetal as compared with adult life, the arterial walls contain a greater proportion of smooth muscle. Postnatally, there is rapid thinning – in the first 2 weeks, due to distension, and over the next year, due to a slow reduction in the number of muscle fibres (Hislop and Reid 1981). If such remodelling does not occur, the pulmonary vascular resistance (PVR) remains high, leading to persistent pulmonary hypertension (p. 495). Abnormal remodelling alters the pulmonary vascular reactivity and the response to pharmacological agents. Normal postnatal development can be divided into three overlapping phases (Hall and Haworth 1986; Haworth 1992). Stage 1 starts from birth and lasts for about 4 days, and represents adaptation to extrauterine life. The vessel walls become thinner (Haworth et al. 1987). Initially, the endothelial cells are squat, have a low surface-to-volume ratio and have many surface projections, but, within 5 minutes after birth, the endothelial cells become thinner with less cell-to-cell contact; fewer projections are evident as their surface membrane material is donated to allow the cells to spread rapidly (Fig. 27.2). During stage 2, when the cells have taken up their definitive position, they deposit connective tissue and fix the wall structure. In stage 3, there is growth of the pulmonary vasculature, which lasts until adulthood. At birth, almost the entire pulmonary vasculature is innervated. The majority of nerves contain the vasoconstrictor neuropeptides tyrosine and tyrosine hydroxylase (Haworth 1992). Both nerve density and the immunoreactive

Fig. 27.2 Illustration of en face shape changes – the spreading of endothelial cells from birth to 3 days. (Reproduced from Haworth (1992).)

expression of the neurotransmitters increase particularly rapidly in the first 2 weeks (Wharton et al. 1988).

Cardiorespiratory adaptation at birth

Aeration of the lungs at birth

In fetal life, the respiratory system is fluid-filled. The replacement of lung liquid by air is largely accomplished within a few minutes of birth. Lung liquid production ceases during labour; that effect is mediated by catecholamines (Walters and Olver 1978) and arginine vasopressin (Hooper et al. 1993). Some liquid is squeezed out under the high vaginal pressure during the second stage of delivery (Karlberg et al. 1962), while the majority is absorbed into the pulmonary lymphatics and capillaries (Strang 1977). The transpulmonary pressure, which inflates the lungs, displaces liquid from the terminal respiratory units into the perivascular spaces. Air entry into the lung displaces liquid and reduces the hydraulic pressure in the pulmonary circulation, increasing blood flow. This increases the effective vascular surface area for fluid exchange, facilitating water absorption into the pulmonary vascular bed.

Stimulus for the first breath

Fetal breathing activity ceases during labour. Following birth, one of the most important stimuli to the onset of breathing is cooling. Audiovisual, proprioceptive and touch stimuli recruit central neurons and increase central arousal (Condorelli and Scarpelli 1975; Hasan and Rigaux 1992). Hypoxia mediated by central chemoreceptors is important, but peripheral chemoreceptor activity

is not critical to the onset of respiration (pp. 454–455). The median time for the onset of respiratory activity is 10 seconds (Vyas et al. 1981).

A high negative pressure is required to overcome the high flow resistance and inertia of liquid in the airways, as well as the surface tension at the air–liquid interface (Karlberg et al. 1962). Both Karlberg et al. (1962) and Milner and Saunders (1977) recorded inspiratory pressures during the first breath of greater than 20 cmH₂O, but not in all infants. Subsequently, using a dual-pressure tip transducer, Vyas et al. (1986) demonstrated that pressures of greater than 20 cmH₂O were the norm. Expiration is active for the first few breaths, with pressures ranging from 18 to 115 cmH₂O; this may aid the distribution of ventilation and facilitate further fluid clearance from the lungs.

Changes in lung mechanics after birth

There is a fall in airways resistance and rise in functional residual capacity (FRC), which is most rapid in the first 2 hours. Compliance, however, progressively increases over the 24-hour period as lung liquid is gradually absorbed. The changes in lung mechanics occur at a slower rate following elective caesarean section, when there is a delay in lung fluid absorption.

Circulatory changes at birth

In the fetus, only about 12% of the right ventricular output enters the pulmonary circulation (Friedman and Fahey 1993), because of the high PVR, the presence of a patent ductus arteriosus and the low-resistance placental component of the systemic circulation. At birth, clamping of the umbilical cord and removal of the placenta from the circulation reduce venous return through the inferior vena cava to the right atrium. The foramen ovale closes because of the resultant lower right atrial pressure and the increase in left atrial pressure that occurs with the increased pulmonary venous return. The loss of the umbilical venous return also means diminished flow through the ductus venosus and passive closure occurs usually within 3–7 days of birth.

PVR falls rapidly in the first minutes after birth, then more gradually over the next days and weeks of life. This fall in PVR, which is associated with a structural reorganisation and thinning of the vessel walls, allows for an eightfold increase in pulmonary blood flow. There are several mechanisms responsible for the fall in PVR. Lung aeration results in opening up the pulmonary capillary bed, acute lowering of PVR and an increase in pulmonary blood flow. This is due to both a mechanical effect and oxygenated blood passing through the pulmonary circulation. In fetal lambs, mechanical expansion of the lungs with a non-oxygenated gas caused a decrease in PVR and a fourfold increase in pulmonary blood flow; a further increase resulted when oxygen was used as the ventilatory gas (Tietel et al. 1987). Inflation of the lungs also stimulates pulmonary stretch receptors, which leads to reflex vasodilation of the pulmonary vascular bed. Mechanical expansion additionally creates surface forces at the gas–liquid interface within the alveoli, which physically expand small blood vessels and decrease perivascular pressure (Walther et al. 1993).

Prostaglandins and endothelial-derived products (endothelin-1 and nitric oxide (NO)) are important in regulating fetal and transitional pulmonary vascular tone (Table 27.2) (Shaul 1995; Zenge et al. 2001). The fetal PVR is high because of the low oxygen tensions and low prostaglandin (PG) I₂ and NO levels and the presence of vasoconstrictor substances such as endothelin-1. In healthy infants, the majority of measurable changes in cardiopulmonary haemodynamics occur by 8 hours, although some degree of

Table 27.2 Factors that modulate pulmonary vascular resistance (PVR) in the near-term and term transitional and neonatal pulmonary circulation

LOWERS PVR	INCREASES PVR
Endogenous mediators and mechanisms	
Oxygen	Hypoxia

right-to-left ductal shunting may be found up to 12 hours after birth (Walther et al. 1993). In most infants the ductus has closed or is closing by 24 hours of age, but there is a significant delay in ductal closure in infants with respiratory failure and pulmonary hypertension. During early neonatal life, the pulmonary circulation remains unstable, and in certain disease states, particularly those associated with asphyxia or chronic hypoxia, the PVR increases or remains at the high fetal levels – persistent pulmonary hypertension (pp. 495–500).

Postnatal function

The airways

The nasal portion of the airway is supported by its larger bony and smaller cartilaginous portions. Nasal resistance to airflow, which

constitutes approximately one-third of the total pulmonary resistance, is determined by the physical dimensions in a given individual, which are related to ethnic origin (Ohki et al. 1991), and the state of the mucous membranes lining the airway. The prime function of the nose is to act as an entry port for respiration, humidifying and warming inspired gas and trapping extraneous particles. Infants are not necessarily obligate nose breathers and full-term infants can establish oral breathing in the presence of nasal occlusion (Rodenstein et al. 1985). The pharyngeal portion of the airway is very compliant.

Chemoreceptors in the larynx serve to prevent the entry of foreign material by triggering reflex apnoea. Changes in laryngeal diameter modulate airway resistance and lung volume can be maintained by expiratory adduction of the vocal cords (Duara 1992). Laryngeal resistance can be varied by active abduction of the vocal cords during inspiration and by passive as well as active adduction during expiration. Inspiratory abduction and expiratory adduction of the vocal cords occur during FBMs.

The trachea and main bronchi are supported by cartilaginous rings; nevertheless, smooth-muscle contraction can cause narrowing and markedly increase resistance, at least in the adult. In the newborn, the small airways are more compliant than in the adult and expiratory collapse tends to lead to air trapping.

The thorax

In the newborn, compared with the adult, the thorax is round rather than dorsoventrally flattened and the rib orientation is horizontal rather than caudal, thus the expansion potential of the thorax is limited. The neonatal thoracic cage has relatively soft and flexible bony elements, which makes the chest wall subject to collapse during increased inspiratory efforts and the lungs rather collapsed at rest. To compensate, the infant attempts to elevate lung volume at end expiration by a rapid breathing rate, a short expiratory time, intercostal activity and grunting (expiratory laryngeal adduction). Grunting disappears in rapid eye movement (REM) sleep (Harding 1986). Instability of end-expiratory lung volume, particularly in the premature neonate, may explain fluctuations in arterial oxygen levels (Asonye and Vidyasagar 1981).

The respiratory muscles (Fig. 27.3)

The main inspiratory muscle is the diaphragm, a dome-shaped muscle attached to the ribs. Diaphragmatic contraction results in the abdominal contents moving downwards, increasing the vertical dimension of the thoracic cavity. If the dome's descent is impeded by abdominal pressure, then the lower ribs are pulled up. This increases the ribcage diameter by virtue of the linkages between ribs provided by the intercostal muscles and by the articulations of the ribs that lead to the 'pump and bucket handle action'. The configurations of the adult and neonatal diaphragm differ, the latter being relatively flat following birth, the dome shape developing with the physical growth of the thorax and internal organs (Devlieger 1987). There is an exaggerated asymmetrical movement of the newborn diaphragm during respiration. These differences mean the diaphragm is less efficient in the neonate than in the adult. The number of skeletal muscle fibres in the diaphragm is, however, fixed at the time of birth and the subsequent increase in muscle weight is due to hypertrophy. The diaphragm consists of: (1) type I fibres, which are oxidative with a slow twitch and fatigue-resistant; (2) type IIa fibres, which are oxidative-glycolytic with a fast twitch but also fatigue-resistant; and (3) type IIb fibres, which are glycolytic with a fast twitch and are fatigable (Woodrum 1992).

The proportion of type I fibres is low at birth and increases until 6 months of age; there is an associated increase in type IIb, but a decrease in type IIa fibres. Type IIc fibres, which are present at birth, disappear completely by 6 months (Mayock et al. 1987). This means that at birth the diaphragm has a relatively high percentage of oxidative fibres (type I, IIa and IIc) which are fatigue-resistant. The proportion of type I fibres, however, may be low in the preterm infant, putting the baby at risk of diaphragmatic muscle fatigue. Optimal function of the diaphragm is dependent on ribcage stability and adequate abdominal muscle tone. This is particularly important when the system is loaded, as with stiff lungs or obstructed airways.

Upper airway muscles

Patency of the upper airway is dependent on the upper airway muscles and the diaphragm. There is active contraction of the laryngeal muscles, particularly in early expiration, and there is relatively late relaxation of the inspiratory muscles. That activity reduces the flow rate and is modified by carbon dioxide levels; high levels result in a reduced resistance to flow. If the FRC is reduced, the above muscle activity is increased, such that the airway is almost completely occluded in expiration and gas has to be forced out by contraction of the abdominal muscles, producing a grunt.

Gas exchange in the neonatal lung

At rest, oxygen consumption in the newborn (7 ml/min/kg) is approximately twice that of adults. Minute ventilation is proportionally increased and is achieved largely by an increased breathing rate. The rate is increased because there are constraints on increasing tidal volume imposed by the relatively stiff lungs and unstable ribcage. The disadvantage, however, of increasing rate is that this increases the amount of dead-space ventilation, although the proximal airways have a relatively low volume (Mortola 1983). Overventilation or underperfusion of some lung units contributes to the wasted ventilation. The contribution of ventilation-perfusion mismatch, as estimated from the arterial-alveolar differences for oxygen ($a\text{-ADo}_2$), is most marked in preterm infants in the first hours after birth.

A major difference between the blood gases of newborn and older infants is the lower PaO_2 in relation to the inspired oxygen tension. This is largely because of right-to-left shunting of blood either through areas of the lung with very low ventilation-perfusion ratios or, less commonly, through persisting fetal vascular channels (foramen ovale and ductus arteriosus). Estimates of the total shunt in healthy infants are 24% of the cardiac output in the first hour after birth and 10% at 1 week of age. Shunting through fetal vascular channels is important immediately after birth in immature infants or in sick infants with raised PVR. The low PaO_2 due to right-to-left shunting (through cardiac shunts and perfused but non-ventilated lung units) cannot be overcome by administering 100% oxygen, because the blood that is being ventilated soon becomes fully saturated and increasing the oxygen tension adds little further oxygen. On the other hand, carbon dioxide accumulation from partial right-to-left shunting can be compensated for by increased ventilation of functioning lung units. Thus, provided respiratory efforts are maintained, PaCO_2 will be normal or even low, despite right-to-left shunting.

Fig. 27.3 Diagrammatic representation of the respiratory pump showing the various muscles and actions that make up inspiration. Although the diaphragm is the main muscle, many others act to optimise its function by opening the airways and splinting the floppy ribcage.

Gas transport in the blood (Delivoria-Papadopoulos and Di Giacomo 1992)

Oxygen

Haemoglobin increases the oxygen transport capacity of the blood 70-fold over that of plasma. As a consequence, the majority of oxygen in whole blood is transported as oxyhaemoglobin (HbO_2) and only a small proportion is dissolved in solution. The haemoglobin concentration is regulated by a renal sensing mechanism, which operates to maintain a balance between the oxygen supply and requirement of the renal tissues. A decrease in concentration or arterial oxygen saturation of haemoglobin or an increase in haemoglobin affinity for oxygen increases erythropoietin production. Haemoglobin is a tetramer: each of the four subunits contains a haem moiety (porphyrin and one atom of ferrous iron) attached to a polypeptide (globin) chain. The four iron atoms can each combine with an oxygen molecule; they remain in the ferrous state, that is, the reaction is oxygenation rather than oxidation. In adult haemoglobin, the four globin chains are predominantly $\alpha_2\beta_2$ (HbA), whereas in the fetus they are $\alpha_2\gamma_2$ (HbF). The quaternary structure of haemoglobin determines its affinity for oxygen: uptake

of oxygen by haemoglobin results in a change of position of the haem moieties, facilitating further oxygen binding. The result is that the oxygen–haemoglobin dissociation curve (the relationship of the percentage oxygen saturation of haemoglobin to the P_{O_2}) has a characteristic sigmoid shape. The oxygen–haemoglobin dissociation curve is affected by the pH, temperature and concentration of 2,3-diphosphoglycerate (2,3-DPG). A rise in temperature or fall in pH (Bohr shift) shifts the curve to the right, which means that a higher P_{O_2} is required for haemoglobin to bind to a given amount of oxygen. This is quantified as the P_{50} , the P_{O_2} at which the haemoglobin is half saturated with oxygen. The higher the P_{50} , the lower the affinity of haemoglobin for oxygen. 2,3-DPG is formed from a product of glycolysis and thus its concentration falls when the pH is low. 2,3-DPG binds preferentially to the β chains of deoxygenated haemoglobin. An increase in 2,3-DPG causes more oxygen to be liberated, that is, the oxygen dissociation curve is shifted to the right.

The fetus and newborn

Compared with in the adult, fetal red blood cells (RBCs) are larger, have a shorter half-life and differ in ultrastructure. They also differ

with regard to their mechanical, osmotic, thermal and acidic fragility, and contain haemoglobin F (HbF), which is less easily denatured in alkaline or acidic solutions than is adult haemoglobin. The γ chains of HbF have the same number of amino acids as the β chains, but differ in sequence by 39 amino acids. The γ chains of HbF have poorer binding to 2,3-DPG. The effect of 2,3-DPG on the P_{50} of fetal haemoglobin is approximately 40% of the effect on the P_{50} of adult haemoglobin. The oxygen tension of fetal blood is one-fifth to one-quarter that of the adult, but the fetal arterial blood oxygen content and oxyhaemoglobin saturation are similar to those of the adult. This results from the high oxygen-carrying capacity and the increased oxygen affinity of HbF. The latter facilitates the movement of oxygen from mother to fetus. Oxygen delivery to the fetal tissues is sustained because the steep fetal oxygen dissociation curve means that a small decrease in oxygen tension results in a major change in oxyhaemoglobin saturation and unloading of oxygen.

In the term newborn, 70–80% of the haemoglobin is HbF; in preterm babies, about 90% of haemoglobin is HbF. Birth, intra-uterine hypoxia and haemolytic disease of the newborn do not cause a change in the proportions of HbA and HbF at any given gestational age. Near term, however, the demand for accelerated erythropoiesis leads preferentially to synthesis of HbA. During the first year, HbF decreases from 70% to less than 2% of the total haemoglobin.

The high oxygen affinity of HbF has disadvantages in postnatal life. In particular, the low P_{50} decreases the driving potential for oxygen diffusion, limiting the rate at which oxygen can be unloaded (Altura and Chand 1981). The oxygen consumption of the newborn at minimal activity, even in a thermally neutral environment, increases by 100–150% in the first few days. To meet these demands, the baby's blood oxygen affinity decreases rapidly over the first 5 days and then more gradually, reaching adult values by 6 months (Delivoria-Papadopoulos et al. 1971). During the first 5 days, the 2,3-DPG levels rise to above those found in the adult; this decreases blood oxygen affinity by lowering intercellular pH. Prematurely born babies have a lower 2,3-DPG content, lower P_{50} and higher fetal haemoglobin concentration. They have a smaller oxygen unloading capacity and do not catch up until 3 months of age (Guyton 1971).

Carbon dioxide

Carbon dioxide is 20 times more soluble in water than is oxygen. Carbon dioxide is carried in the blood by three mechanisms: the majority as bicarbonate (85%), but also dissolved and in combination with proteins as carbamino compounds. Bicarbonate is formed very rapidly in RBCs, because of the presence of carbonic anhydrase, which catalyses the first part of the following reaction:

Ionic dissociation of H_2CO_3 is fast. HCO_3^- then diffuses out of the RBC down a concentration gradient, but H^+ cannot follow and binds to haemoglobin. This is facilitated in the presence of reduced haemoglobin, which is a weaker acid than oxyhaemoglobin, and thus deoxygenation of the blood increases its ability to carry carbon dioxide (the Haldane effect). To maintain electrical neutrality, as HCO_3^- diffuses out, Cl^- diffuses into the RBC (the chloride shift). These events increase the osmolar content of the RBC, thus the packed cell volume is higher on the venous than on the arterial side of the circulation. Carbon dioxide also combines with the N terminals of amino acids of proteins, particularly haemoglobin, to form carbamino compounds:

The newborn's blood has a greater carbon dioxide transport capacity. This is because of the high haemoglobin level. In addition, carbon dioxide competes with 2,3-DPG for the haemoglobin binding site, and, since 2,3-DPG binds less avidly with HbF than with adult haemoglobin, more carbon dioxide can be taken up. RBC carbonic anhydrase levels, however, are 25% lower in the neonate and even more so in those born prematurely (Kleinmann et al. 1967).

Regulation of breathing

The rhythmic transition from the inspiratory to the expiratory phase of the respiratory cycle is ordered by a centrally generated respiratory rhythm, which consists of three neural phases:

1. inspiration, corresponding to inspiratory muscle contraction
2. phase 1 expiration, corresponding to postinspiration or passive expiration, when inspiratory muscles cease to contract progressively
3. phase 2 expiration, corresponding to active exhalation with expiratory muscle contraction.

Respiratory 'centre'

The respiratory rhythm (described above) is generated by a loose complex of respiratory neurons, which lie within the ventrolateral region of the brainstem. The respiratory rhythm generator also produces sighs and gasps. A variety of models of the central respiratory rhythm generator have been proposed, but a common assumption is that chemical neurotransmission is required to mediate the synaptic interactions which play a role in generation of transmission and expression of the respiratory rhythm. Respiratory rhythm-generating areas, such as the pre-Boetzinger complex, receive multiple inputs from many areas outside and within the vicinity of the complex (Doi and Ramirez 2008). Afferents from the forebrain, hypothalamus, central and peripheral chemoreceptors, muscles, joints and pain receptors are integrated into the 'centre'. The number of intersynaptic connections reaches a peak towards the end of fetal life. The complex projects to various respiratory-related areas that contain neuromodulators which are in turn modulated by multiple other areas. Most areas contain multiple neuromodulators that are partly released from the same neurons, thus neuromodulation occurs at all levels of integration (Doi and Ramirez 2008).

Neurotransmitters

Excitatory

The excitatory neurotransmitters include glutamate, which excites NMDA and non-NMDA receptors; the latter are involved in generating and transmitting respiratory rhythms to spinal and cranial respiratory neurons (Funk et al. 1993). The transmission of inspiratory drive is further fine-tuned by presynaptic glutaminergic modulation at the level of the spinal cord. Serotonin (5-hydroxytryptamine (5-HT)) neurons in the medulla oblongata constitute a critical system in the modulation of autonomic and respiratory effector neurons (Paterson and Darnall 2009). 5-HT has diverse effects on respiratory neuronal activity, but the most consistent effect is to restore a normal breathing pattern in metabolic states such as hypoxia or ischaemia, which cause apneustic breathing (Lalley et al. 1994). The developmental profile of 5-HT_{2A} receptors changes over the first year after birth in the hypoglossal nucleus critical to airway patency (Paterson and Darnall 2009).

Inhibitory

Both gamma-aminobutyric acid (GABA) and glycine are essential for generating respiratory rhythm in the primary network. GABA and glycine are released by late and postinspiratory neurons to turn off inspiratory neurons and so facilitate the transition from inspiration to expiration. Adenosine is ubiquitously formed in the body and has both central and peripheral effects. When administered centrally, it depresses ventilation; this effect is most pronounced in young full-term and preterm animal models. If adenosine is given systemically, however, it stimulates breathing, probably by stimulating peripheral chemoreceptors; this effect may be more important in the adult. Adenosine antagonists (theophylline and caffeine) stimulate breathing and also block – but not in humans – hypoxia-induced respiratory depression (Runold et al. 1989).

Chemoreceptors

Both central and peripheral chemoreceptors are involved in modification of respiratory activity in response to changes in blood gases. The central chemoreceptors are situated near the ventral surface of the medulla and respond to changes in carbon dioxide/pH and oxygen supply. The peripheral chemoreceptors are situated at the bifurcation of the common carotid arteries (carotid bodies) and in the aortic bodies above and below the aortic arch, the former being more important in humans.

In the fetus, the arterial chemoreceptors are active in utero, but have reduced sensitivity. They are virtually silenced when the arterial PO_2 rises at birth (Blanco et al. 1984). Resetting of the carotid chemoreceptors to hypoxia then occurs. This is probably triggered by the rise in blood oxygen levels. The resetting of the chemoreceptors to hypoxia is essentially complete within 24–48 hours of birth (Calder et al. 1994) and may be due to a change in dopamine levels. Dopamine inhibits chemoreceptor discharge in both the newborn and adult. If rat pups are delivered into a hypoxic environment (12%), they maintain both their low sensitivity to hypoxia, with persistence of the immature inhibitory response to hypoxia (Eden and Hanson 1987), and a high dopamine turnover. In the lamb, hyperoxia induced by mechanical ventilation of the fetus for a few days before birth causes premature resetting (Blanco et al. 1987).

Responses to changes in oxygen tension (Fig. 27.4)

The fetus

Fetuses respond to hypoxia with a suppression of ventilation, which is most marked in growth-retarded fetuses (Bekedam and Visser 1985); the hypoxic suppression of ventilation is mediated by the lateral part of the lower pons. In response to hypoxia there are also cardiovascular reflexes; these include bradycardia and redistribution of the circulation to favour the heart, brain and adrenals, which minimise oxygen consumption and conserve oxygen supplies for vital organs. Hyperoxia stimulates continuous fetal breathing.

The newborn

The newborn's response to hypoxia in the perinatal period is a biphasic response: a transient increase in minute ventilation followed by a decrease to or below baseline levels. The initial increase in ventilation is probably due to activation of peripheral chemoreceptors, as it is abolished by carotid sinus nerve section. The subsequent reduction in ventilation may result from a fall in $Paco_2$

Fig. 27.4 Diagrammatic representation of the age-related responses to hypoxia, induced by breathing hypoxic gases for 5 minutes (solid lines). Breathing efforts assessed by diaphragmatic electromyogram in the fetus and by ventilatory responses in others. The dashed line indicates that apnoea may occur in preterm infants, resembling a fetal response. (Reproduced from Henderson-Smart (1983).)

following the initial hyperventilation and may be due to a depression of central respiratory neurons (Rigatto et al. 1988). It may also be explained by the suppressant effect of hypoxia in the fetal state persisting into the neonatal period. The biphasic response to hypoxia disappears at 12–14 days and the adult pattern is then seen, that is, stimulation without depression (Fig. 27.4). Very immature infants respond to hypoxia in a similar fashion to fetuses, that is, with apnoea. This inhibition of breathing is at a suprapontine level. More mature preterm infants have an initial increase (but less than in term infants) and then a more dramatic fall in ventilation in response to hypoxia (Rigatto 1992). In non-REM sleep, the decrease in ventilation is the predominating response. The response to hypoxia is also modified by the temperature of the environment in which the infant is nursed; transient hyperventilation on exposure to 12% O_2 is not seen if the infant is in a cold rather than a warm environment (Ceruti 1966).

A hyperoxic gas causes a temporary suppression of breathing; this is attributed to the withdrawal of peripheral chemoreceptor drive. During the first few days, the reduction in ventilation with 100% oxygen is less, consistent with inactivity of the carotid afferents during this resetting period. After a few minutes of hyperoxia, ventilation increases to above control levels. In adults, a similar but less marked hyperventilation has been attributed to hyperoxic cerebral vasoconstriction, which leads to increased brain tissue carbon dioxide. The response to hyperoxia is slower in more immature infants. Prolonged exposure to supplemental oxygen also reduces the response to hyperoxia.

Response to carbon dioxide/acidosis

The fetus

Fetal breathing can be detected as early as 14 weeks of gestation in the human. The amount of time the fetus spends breathing increases

with advancing gestational age. Initially, fetal breathing was thought to depend only on behavioural reflexes, as it was only observed during REM sleep. It is now known that fetal breathing is modified by chemical stimuli; the fetus responds to an increase in PaCO_2 with an increase in breathing, both elevated frequency and diaphragmatic activity. It is probably that the hydrogen ion concentration, rather than carbon dioxide per se, is the major stimulus to respiratory activity, although there is some evidence that carbon dioxide may have an effect independent of pH (Millhorn and Eldridge 1986). During non-REM sleep, however, only very high PaCO_2 levels (>100 mmHg) can initiate breathing activity (Rigatto et al. 1988). Hypoxia inhibits fetal breathing. Lesions in the ventrolateral pons eliminate the hypoxic inhibition of breathing and are associated with a lower threshold for carbon dioxide drive-augmented breathing through all states (Johnston et al. 1989). Fetal breathing is also suppressed during labour.

The newborn

Inhalation of CO_2 increases ventilation in the newborn in both REM and quiet sleep. The slope of minute ventilation versus PaCO_2 levels in the newborn is similar to that of adults, but the response is shifted to the left because of lower resting carbon dioxide levels (Rigatto 1984). The tidal volume component of the ventilatory response assumes greater importance with postnatal development. The percentage of inhaled CO_2 influences the pattern of breathing. A low percentage of CO_2 (2%) primarily stimulates an increase in tidal volume (Kalapesi et al. 1981), whereas a higher percentage provokes an increase in respiratory frequency and tidal volume (Morielle et al. 1985). Periodic breathing is abolished with a small increase in inhaled CO_2 (Kalapesi et al. 1981). Sleep state also influences the response to carbon dioxide, both in adults (Phillipson and Bowes 1986) and in the newborn. In term infants, the slope of ventilatory response is less during active than quiet sleep (Fig. 27.5). This may be due to mechanical instability associated with ribcage distortion in active sleep, since the diaphragmatic response is intact. In preterm infants (Rigatto et al. 1991), the slope of the ventilatory response is less, but increases with postnatal growth. As diaphragm electromyogram responses to CO_2 inhalation are also reduced in the preterm infant, this is probably due to the immaturity of the central chemoreceptors rather than mechanical differences in the respiratory pump (Rigatto 1984).

Respiratory reflexes

The Hering–Breuer reflexes

Hering and Breuer (1868) described three respiratory reflexes. The Hering–Breuer inflation reflex is stimulated by lung inflation and results in cessation of respiratory activity. This reflex is generated by stretch receptors within the airway and has an afferent pathway lying within the vagi. In the newborn, the reflex produces a pattern of rapid, shallow tidal breathing and operates within the tidal volume range. The reflex is active from FRC and is maximal after an inspiration of approximately 4 ml/kg above FRC (Hassan et al. 2001).

The Hering–Breuer expiratory reflex is stimulated if inhalation is prolonged. The active expiration seen in infants ventilated at slow rates and long inflation times may be a manifestation of this reflex (Greenough 1988).

In animal models, the Hering–Breuer deflation reflex is evidenced by a prolonged inspiration generated in response to deflating the lung rapidly, either by attaching the endotracheal tube to a suction source or creating a pneumothorax, or following an unusually vigorous expiratory effort which takes the lung below its end-expiratory level. This response does occur in the newborn (Marsh et al. 1994) and may have a role in maintaining the FRC. The strength of the reflex is increased if rapid lung volume reduction is commenced at FRC rather than end inspiration (Hannam et al. 2001).

Head's paradoxical reflex

Head (1889) noted that, if vagal conduction was blocked, rapid inflation, instead of producing apnoea, resulted in a stronger and more pronounced diaphragmatic contraction; this was named Head's paradoxical reflex. It has subsequently been termed the inspiratory augmenting reflex or provoked augmented inspiration and is the underlying mechanism of the first breath and sighing. This reflex improves compliance and reopens partially collapsed airways. It has an important role in promoting lung expansion during resuscitation. Its frequency is increased by low compliance, hypercapnia and hypoxia (Cherniack et al. 1981).

The intercostal phrenic inhibitory reflex

Rapid chest wall distortion results in a shortening of inspiratory efforts. This reflex response is inhibited by an increase in FRC or

Fig. 27.5 The ventilatory response to CO_2 rebreathing in neonates. Note that (A) preterm and (B) term infants showed a decreased response to CO_2 in 'phasic' rapid eye movement sleep as compared with quiet sleep. The vertical axis on the figures in (B) is a measure of electromyogram (EMG) activity multiplied by the change in respiratory rate. (Reproduced from Rigatto (1992).)

applying continuous positive airway pressure; the mechanism may be improved chest wall stability (Martin et al. 1977).

Irritant reflexes

Subepithelial chemoreceptors in the trachea, bronchi and bronchioles detect insults to the epithelial surfaces; thus, inhalation of toxic gases causes a change in frequency and depth of respiration. The response is less in REM sleep and in the premature infant (Fleming et al. 1978), who has a smaller number of small myelinated vagal fibres and poorly developed receptors.

Upper airway reflexes

Breathing is stimulated by cold via the trigeminal afferents of the facial skin, whereas irritant stimuli to the nasal mucosa cause inhibition of breathing and cardiovascular reflex responses resembling those in diving mammals. The latter response is enhanced under anaesthesia and in the newborn (Wealthall 1975), when cortical dampening of the responses is reduced. Vigorous suctioning of the nasopharynx can stimulate apnoea and bradycardia via these reflexes (Cordero and Hon 1971).

The laryngeal chemoreceptors defend the lower airway from inhalation. Introduction of water into the interarytenoid notch induces apnoea (Pickens et al. 1989). In active sleep, laryngeal stimulation is more likely to induce apnoea and less likely to cause arousal (Phillipson and Bowes 1986). This is of potential clinical significance since gastro-oesophageal reflux is more common during active sleep (Jeffery et al. 1980). Maturation of the laryngeal chemoreflex is characterised by an increase in coughing and a decrease in swallowing and apnoea (Thach 2007). Those changes are probably

the result of central processing of afferent stimuli rather than of a reduction in sensitivity or change in receptor distribution in the larynx (Thach 2007).

Lung mechanics (Table 27.3)

Lung volumes

The tidal volume is the amount of gas entering or leaving the lung with each breath. Minute volume is calculated by multiplying the tidal volume by the respiratory rate over 1 minute. The volume exchanged following a maximum inspiratory and expiratory effort is called the vital capacity and in the infant can be measured during crying (crying vital capacity), or more accurately by pressurising a face mask to 20–25 cmH₂O and then inflating a rigid walled jacket with pressures of 40–60 cmH₂O (Turner et al. 1995). The residual volume remains after a maximum expiratory effort; residual volume plus vital capacity gives the total lung capacity. At end expiration, the volume of gas remaining in the lung is referred to as the FRC and can be estimated by rebreathing an inert gas, such as helium (FRC_{he}). Only areas of the lung in communication with the airways will be measured by such a method. Alternatively, the patient can be placed in a body plethysmograph and the FRC_{pleth} estimated by applying Boyle's law during airway occlusion; FRC_{pleth} is FRC_{he} plus trapped gas. The dead space is the part of the respiratory system which does not take part in ventilation and is made up of the anatomical dead space (the conducting airways) and the physiological dead space, which includes non-functioning alveoli. Alveolar ventilation can be estimated from the tidal volume minus the dead space. In infants with respiratory distress, particularly transient

Table 27.3 Lung mechanics in healthy babies

Measurements	NO. OF INFANTS STUDIED	MEAN	STANDARD DEVIATION	RANGE
Tidal volume (ml/kg)	266	4.8	1.0	2.9–7.9
Respiratory rate (breaths/min)	266	50.9	13.1	25–104
Minute volume (ml/min/kg)	266	232	3.6	78–444
Dynamic compliance (ml/cmH ₂ O/kg)	266	1.72	0.5	0.9–3.7
Total pulmonary resistance (cmH ₂ O/l/s)	266	42.5	1.6	3.1–171
Work of breathing (G.cm)	266	11.9	7.4	1.1–52.6
Expiratory time (s)	291	0.57	0.17	0.27–1.28
Inspiratory time (s)	291	0.51	0.10	0.28–0.87
Time to maximum expiratory flow/total expiratory time (s)	291	0.51	0.12	0.18–0.83
Static compliance (ml/cmH ₂ O/kg)	299	3.70	1.45	2.0–14.8
Respiratory system resistance (cmH ₂ O/l/s)	299	63.4	16.6	34.9–153.3
Time constant of respiratory system (s)	299	0.24	0.10	0.08–1.1
Thoracic gas volume (ml/kg)	271	29.8	6.2	14.5–45.6

Data of Milner and Marsh, reproduced with their permission (1999).
The tidal flow and volume were measured by a type 00 Fleisch pneumotachograph, and intrathoracic pressure with a 4-cm oesophageal balloon. Babies supine and in quiet sleep. Dead space eliminated by a bias flow of air.

tachypnoea of the newborn, the respiratory rate is increased and the tidal volume may be decreased. In respiratory distress syndrome (RDS) and pneumonia, the FRC is low and the physiological dead space increased.

Compliance

Compliance is a measure of the distensibility of the lungs and chest wall, the change in volume per unit pressure. Dynamic compliance is assessed during tidal breathing by measurement of the change in volume (usually using the integrated signal of a flow-measuring device, a pneumotachograph) divided by the change in pleural pressure (which under certain conditions is similar to the change in oesophageal pressure) between points of zero airflow (Fig. 27.6). In situations with a rapid respiratory rate and chest wall distortion, dynamic compliance measurements can be inaccurate. Dynamic compliance is measured in ventilated infants by relating the volume change from a positive pressure inflation to the pressure drop (that is, positive inflation pressure – positive end-expiratory pressure), providing that the infant is not making spontaneous respiratory efforts, as these might interfere with volume delivery during inflation.

Static compliance requires the measurement of changes in lung volume over a larger range than the tidal volume or an assumption has to be made that the end-expiratory transpulmonary pressure represents a static value, which is unlikely to be true in infants with lung disease (Silverman 1983). Static compliance is usually measured in spontaneously breathing infants using an occlusion technique, which relies on occlusion at end inspiration causing a transient inhibition of breathing by stimulation of the Hering-Breuer reflex. The airway pressure during the occlusion is related to the volume above end expiration at which the occlusion was made. This technique requires temporary cessation of breathing, which

Fig. 27.6 Volume and oesophageal pressure traces during spontaneous breathing. The dynamic compliance is calculated by dividing the tidal volume (δ_v) by the pressure gradient between the beginning and end of inspiration (δ_p). (Reproduced from Greenough et al. (1995).)

may be difficult to provoke in an infant with a rapid respiratory rate or a weak Hering-Breuer reflex. Static compliance measurements assess the compliance of both the lung and chest wall. In the newborn, the chest wall compliance is very high, so, essentially, dynamic and static compliance values are similar. Compliance is reduced in infants with RDS.

Resistance

Resistance is a measure of the pressure necessary to generate airflow. Airway resistance can be assessed in a body plethysmograph, but after the first week the infant will usually require sedation and this technique is not applicable to oxygen-dependent patients. Pulmonary resistance (Fig. 27.7), however, can be measured on the neonatal intensive care unit, using an oesophageal balloon and pneumotachograph; the pressure difference corresponding to the flow change between points of equal lung volume is measured. Resistance is increased in infants with meconium aspiration syndrome and, at follow-up, in those who required neonatal ventilation (Yüksel and Greenough 1992). Resistance can also be calculated from the volume and flow traces obtained after the release of the occlusion discussed above. The time constant, the time for 63% of the volume to leave the lungs, can be measured; thus, the resistance can be calculated, as the time constant equals the product of the compliance and the resistance (Lesouef et al. 1984).

Fig. 27.7 Flow, volume and pressure traces during tidal breathing. The total pulmonary resistance is calculated by dividing the pressure gradient between midinspiration and midexpiration (δ_p) by the simultaneous flow difference ($\delta_{\dot{v}}$). (Reproduced from Greenough et al. (1995).)

Fig. 27.8 An alveolar type II cell showing two surfactant release mechanisms: lamellar bodies and the constitutive release of surfactant protein A. Surfactant is shown both being phagocytosed by an alveolar macrophage (AM) and being taken back into the cell and reutilised. The inset shows a monolayer which, in the gel phase, is able to withstand very large lateral forces, literally splinting open the alveolus. RER, rough endoplasmic reticulum; LMVB, light multivesicular body; DMVB, dense multivesicular body. (Reproduced from Nicholas *et al.* (1997).)

Surfactant

Origins of surfactant

Alveolar type II cells

Alveolar type II cells produce surfactant (Fig. 27.8) (Post and van Golde 1988). They are compact cuboidal cells, occurring most often at the corners of the air spaces. They cover about 2% of the alveolar surface and account for about 15% of the cell numbers. They differentiate from the columnar epithelium during the canalicular phase of development (p. 448), but are not prominent until about 24 weeks' gestation, when they can be identified by their osmophilic lamellar inclusion bodies (Kuhn 1982). The biosynthesis of surfactant phosphatidylcholine occurs in the endoplasmic reticulum of the type II cell. The phospholipid then moves via intracellular pathways towards the lamellar bodies, for secretion into the alveolus. The characteristic feature of the alveolar type II cell is the lamellar body, storage granules of surfactant (Hallman *et al.* 1976).

Lamellar bodies

A mature lamellar body is about 1.5 μm in diameter. They consist of a limiting membrane surrounding about 20–70 close-packed phospholipid bilayers, or lamellae, each with a width of 66 Å, arranged in a hemisphere. The ends of these lamellae abut on to a baseplate, which is probably an extension of the limiting membrane. In the centre is a matrix core of proteinaceous material (Stratton 1976a, b). Lamellar bodies, isolated from lung tissue by density gradient centrifugation, contain surfactant lipids and the surfactant proteins A, B and C (SP-A, SP-B, SP-C).

Recycling of surfactant

Surfactant may be degraded locally in the alveoli and small airways, the breakdown products being absorbed and recycled by the alveolar cells (Fig. 27.9). More than 90% of the phosphatidylcholine on the alveolar surface is reprocessed; this conserves surfactant components as well as reactivating them to regenerate surfactant. The turnover time is approximately 10 hours (Stevens *et al.* 1989). The contribution, therefore, to the alveolar surfactant pool from de novo synthesis is modest.

There is negative-feedback regulation of surfactant production mediated by SP-A binding to type II cells (Tino and Wright 1998). Surfactant secretion is controlled by stretch receptors and stimulated by gas entering the lung, causing alveolar distension (Rooney *et al.* 1977). Other factors controlling secretion (Rooney 2001) include β -adrenergic receptors on alveolar type II cells, which increase in number towards the end of gestation.

Composition

Surfactant is a complex mixture of substances including phospholipids, neutral lipids and proteins.

Phosphatidylcholine and phosphatidylglycerol

Lipids are the major constituent of surfactant and the most important are phosphatidylcholine (PC) and phosphatidylglycerol (PG), representing 70–80% and 5–10% of the lipids, respectively. Another 10% of the lipids is made up of phosphatidylinositol (PI), phosphatidylserine (PS) and phosphatidylethanolamine (PE). Approximately 60% of the PC has both fatty acids saturated (i.e. disaturated) and, as the primary saturated fatty acid is palmitic acid, the major compound in surfactant is dipalmitoyl phosphatidylcholine (DPPC). The palmitic acid residues are non-polar and hydrophobic and orient towards the air, whereas the PC is polar and hydrophilic and associates with the liquid phase (Ikegami and Jobe 1993). The shape and orientation of the DPPC mean that it generates a stable monolayer and is able to maintain low surface pressures: during expiration the molecules become very closely packed, as the palmitoyl moieties lack the C–C bonds that produce the kinks in the acyl chains (Wright and Clements 1987). DPPC is relatively rigid at body temperature and cannot adsorb to a surface (Goerke 1998); its phase transition (melt) is approximately at 41 °C. At body temperature, DPPC cannot move rapidly enough to maintain a surface monolayer during the respiratory cycle and a 'spreading' agent such as PG is required for normal surfactant function.

PC is synthesised in the endoplasmic reticulum of the type II pneumocytes. There is an increase in surfactant production towards the end of gestation. From 27 to 31 days (term) in rabbits, there is a 10-fold increase in surfactant; during a similar time period, PC increases from 30% to 70% of the total phospholipids, whereas sphingomyelin decreases from 40% to 10%. This change is due to increased synthesis, whereas after birth there is increased secretion. In surfactant from human term and preterm infants, the fractional concentrations of not only DPPC (PC16:0/16:0), but also palmitoylmyristoyl PC (PC16:0/14:0) and palmitoylpalmitoleoyl PC (PC16:0/16:1) increase with maturation (Bernhard *et al.* 2001); in animal models, the concentrations of the last two phospholipids correlate significantly with respiratory rate.

The proportions of the acidic phospholipids PG and PI change with lung development. Initially PI is the primary acidic phospholipid, but with increasing maturation it is replaced by PG. Patients with RDS have low levels of DPPC and absent PG (Hallman *et al.* 1976). In poorly controlled diabetic pregnancies, the fetuses have low levels of PG even near term. If RDS progresses to chronic lung

Fig. 27.9 Illustration of surfactant metabolism based on the saturated phosphatidylcholine component of surfactant. The anabolic pathway for synthesis and secretion links with alveolar transformations of the lamellar surfactant to tubular myelin and the monolayer. Catabolic pathways for phospholipid vesicles are minor pathways in the newborn lung but active in the adult lung. The majority of the surfactant is taken back into type II cells for recycling during the newborn period. MVB, multivesicular body. (Reproduced from Jobe and Ikegami (2001).)

disease, the appearance of PG is delayed; PI also predominated with acute lung.

Other lipids

About 10% of the total lipids in surfactant are neutral lipids. These are cholesterol, triacylglycerols and free fatty acids (Post et al. 1982). They appear to be an integral part of the surfactant in lamellar bodies and on the alveolar surface. Cholesterol alters the fluidity and organisation of lipid-rich membranes. Sphingomyelin represents less than 2% of surfactant lipid, and glycolipids and carbohydrates a very small fraction of the surfactant mass. The amount of sphingomyelin, a minor component of surfactant, remains unchanged through gestation and thus the change in the amount of DPPC or lecithin can be assessed by comparing it with the amount of sphingomyelin. Thus, lung maturity can be assessed by measurement of the ratio of lecithin to sphingomyelin, the L:S ratio (p. 464).

Surfactant proteins

Four surfactant-associated proteins – SP-A, SP-B, SP-C and SP-D – have been identified and constitute 5–10% of surfactant by weight (Dobbs 1989).

Surfactant protein A

SP-A is composed of approximately 248 amino acids (Benson et al. 1985). It is a large glycoprotein belonging to the calcium-dependent

collectin family of proteins. It constitutes approximately 5% of surfactant by weight. There is considerable heterogeneity in its structure because of extensive posttranslational modification. The human gene is located on chromosome 10; gene expression occurs exclusively in type II pneumocytes (Bruns et al. 1987), which appear to be the main site of synthesis (Williams and Benson 1981). Lamellar bodies are enriched with SP-A compared with lung homogenates (O'Reilly et al. 1988).

Synthesis of SP-A increases after 28 weeks of gestation (Batenburg and Hallman 1990). SP-A binds to and confers calcium-dependent aggregation on surfactant phospholipids (Hawgood et al. 1985). SP-A has an essential role in determining the structure of tubular myelin, and the stability and rapidity of spreading and recycling of phospholipids (Veldhuizen et al. 1996). It regulates the synthesis and secretion of phospholipids, and enhances their uptake by type II cells by binding to specific high-affinity receptors on the apical surface of the type II cells. SP-A partially inhibits surfactant secretion from type II cells (Dobbs et al. 1987) and may prevent the accumulation of surfactant on the alveolar surface. SP-A genetic variants have been reported to predispose to or protect from the development of RDS (Bhandari and Gruen 2006). SP-A polymorphisms have been associated with severe RSV infection (Lofgren and Ramet 2002) and an increased risk of bronchopulmonary dysplasia (Weber and Borkhardt 2000).

Surfactant protein B

The active 79-amino-acid SP-B peptide (molecular weight (MW) 7500–9000) is produced by the proteolytic cleavage of pro-SP-B,

a 25 000–33 000 MW precursor protein (Curstedt et al. 1988). SP-B constitutes 1–2% of surfactant by weight (Weaver 1998). The active SP-B peptide contains highly positively charged amino acids that form an amphipathic helix with the hydrophilic amino acid residues positioned near the phospholipid head groups at the membrane surface. It is composed of two identical polypeptide chains, held together by a disulphide bond (Johansson and Curstedt 1997). SP-B is encoded by a single-copy gene located on chromosome 2 (Emrie et al. 1988). The mRNA for SP-B is detectable in human fetal lung tissue as early as 12–14 weeks of gestation, localised in the epithelial cells of bronchi and bronchioles. After 25 weeks it is localised in the type II cells. Glucocorticoids increase expression of SP-B in fetal lung. Expression is restricted to type II pneumocytes and Clara cells. The active SP-B peptide is stored in lamellar bodies and secreted with phospholipids into the airway lumen.

SP-B is required for the formation of tubular myelin and increases the spreading of surfactant phospholipids on to an air–water interface (Chang et al. 1998). SP-B disrupts phospholipid vesicles and alters the ordering and packing of the PC molecules. SP-B combined with lipid mixtures constitutes most of the surface activity of natural surfactant in vitro and increases lung compliance in vivo; SP-C and SP-B together are even more effective. SP-C and SP-B both stimulate lipid uptake in isolated cells. SP-B can also protect the pulmonary surfactant film from inactivation by serum proteins (Friedrich et al. 2000).

Absence of SP-B influences the composition of pulmonary surfactants. It is associated with absence of or markedly decreased PG and an additional aberrant SP-C peptide (Vorbroker et al. 1995). DPPC synthesis is preserved in SP-B deficiency but SP-C cannot be processed to its active peptide and no secretion of normal surfactant occurs (Beers et al. 2000). In SP-B knockout mice, both lamellar bodies and tubular myelin structures are absent. SP-B deficiency, with complete absence of SP-B, is an autosomal recessively inherited disorder (Andersen et al. 2000). SP-B deficiency causes hypoxaemic respiratory failure and leads to lethal respiratory failure within the first year of life and is refractory to mechanical ventilation, surfactant therapy, glucocorticoids and extracorporeal membrane oxygenation (Chetcuti and Ball 1995; Hamvas et al. 1995). It can present as a congenital form of alveolar proteinosis, but not all cases have this feature; pulmonary hypertension is a prominent clinical finding. Lung transplantation is currently the only successful intervention. More than 27 loss-of-function mutations have been identified in the SP-B gene, resulting in lethal neonatal failure. The most frequent mutation is a 121ins2 frameshift mutation, accounting for 60–70% of cases (Bhandari and Gruen 2006). The gene frequency of this mutation is 1 per 1000–3000 (Cole et al. 2000) and the condition is rare – an estimated disease incidence of 1 in 1.5 million births (Clark and Side Clark 2005). Partial deficiencies of SP-B with less severe clinical courses have now been reported (Thompson 2001).

Surfactant protein C

This small hydrophobic protein has a MW of 3000–6000 depending on the separation system used. It constitutes 1–2% of surfactant by weight and is unique to surfactant. The mRNA for SP-C is present from early lung morphogenesis at the distal tips of the branching airways (Wert et al. 1993), but subsequently SP-C expression occurs only in the type II cells. The SP-C gene is located on chromosome 8 (Glasser et al. 1988). SP-C contains 35 amino acids and is likely to be a transmembranous peptide. It has a hydrophobic valine-rich region, which may be required for its function. SP-C can impart

surface-like properties to phospholipids (Revak et al. 1988). Concentrations as low as 1% can dramatically enhance surface adsorption and spreading of phospholipids in vitro. It may play a role in enhancing the reuptake of phospholipids. Surprisingly, SP-C knockout mice have normal respiratory function and lung development (Glasser et al. 2001); it is possible that SP-B replaces SP-C. In humans, however, SP-C deficiency has been associated with an interstitial lung disease (Nogee et al. 2000; Guilot et al. 2009), and, in a Finnish population, SP-C polymorphisms were associated with RDS and premature birth (Lahti et al. 2004).

Surfactant protein D

SP-D has a MW of 46 000 and is produced by type II and bronchiolar epithelial cells. Its expression increases with advancing gestation in association with differentiation of terminal airway cells (Crouch et al. 1991); SP-D production begins in the bronchiolar and terminal epithelium from about 21 weeks of gestation (Mori et al. 2002). SP-D expression is widely distributed in epithelial cells in the body; in the lung, SP-D expression occurs in the type II cells, Clara cells and other airway cells and glands. Glucocorticoids increase SP-D expression. SP-D does not have significant surfactant-like activities when mixed with phospholipids. It is, however, involved in the immune function of the lung (Kuan et al. 1992). SP-D polymorphisms have not been associated with RDS (Clark and Side Clark 2005). Indeed, an association has been found between one variant of the SP-D gene and a lower prevalence RDS; the polymorphism was associated with a lower number of repetitive surfactant doses and a lower requirement for supplementary oxygen on day 28 (Hilgendorff et al. 2009).

Synthesis

Phosphatidylcholine synthesis

PC is produced by the cytidine diphosphate (CDP) choline pathway (Fig. 27.10) (Rooney 1985). Choline is taken up by the cell by facilitated transport and is then phosphorylated by choline kinase to phosphocholine, which in turn is converted to CDP choline (the rate-limiting step), which is then transferred to diacylglycerol to give PC. This produces molecules containing one saturated fatty acid, palmitic acid, and one unsaturated fatty acid, usually oleic acid. This molecule is then remodelled by deacylation to lysophosphatidylcholine, followed by reacylation with a palmitic acid derived from either palmitoyl CoA or a second molecule of lysophosphatidylcholine (Batenburg 1982) to give DPPC. It has been suggested that only 50% of the DPPC is synthesised directly from saturated diacylglycerols as precursors (Paterson and Darnall 2009) and the rest by remodelling. Two remodelling mechanisms exist: both involve deacylation of de novo synthesised 1-saturated-2-unsaturated PC to acyl-2-lysophosphatidylcholine. The latter is then either reacylated by reaction with a saturated acylCoA or transacylated in a reaction involving two molecules of lysophosphatidylcholine (Rooney 1992). Only the former mechanism is quantitatively important. Cholinephosphate cytidyltransferase (CT), which catalyses phosphocholine to CDP choline, is essentially inactive without lipids; CT activity is activated during fetal lung development and after corticosteroid administration. Several other hormones, including thyroid hormones and insulin, and epidermal growth factor (EGF) influence this sequence of events. PC synthesis via the methylation of PE is of minor importance, except in conditions of choline deficiency (Yost et al. 1986).

Fig. 27.10 Pathways in the biosynthesis of phosphatidylcholine, phosphatidylglycerol and phosphatidylinositol. (Reproduced from Rooney (1985).)

Phosphatidylglycerol synthesis

PG is synthesised together with the other acidic phospholipids, PI and PS, from CDP-diacylglycerol, which is in turn derived from phosphatidic acid (Fig. 27.10).

Factors affecting surfactant maturation

Glucocorticoids

Endogenous cortisol is an important physiological stimulus to fetal lung maturation. In the fetal sheep, there is a marked increase in plasma cortisol concentration at the end of gestation and this is associated with an increase in DPPC in lung tissue and lung lavage fluid (DiFiore and Wilson 1994). Administration of betamethasone to pregnant rabbits results in an increase in the total amount of phospholipid, as well as an increase in the percentage of PC in the total phospholipids (Rooney et al. 1979). Cortisol induces fetal lung fibroblasts to produce fibroblast pneumocyte factor, which then stimulates surfactant production by the fetal type II pneumocytes (Smith 1978). In animal experiments, glucocorticoids increase lung aeration, decrease the surface tension of the lung extract and increase synthesis of both surfactant phospholipids and proteins (Kari et al. 1995). In preterm infants, antenatal treatment with dexamethasone increases the surface activity of surfactant isolated from airway specimens and the ratio of SP-A to PC, but not in offspring of mothers with severe hypertension (Kari et al. 1995). Dexamethasone increases pulmonary surfactant secretion through an enhancement of β_2 -adrenoreceptor gene expression (Isohama et al. 1997). In a primary culture of rat alveolar cells, while dexamethasone had no effect on the basal secretion rate of PC, it augmented both the PC secretion and the cAMP formation increased by terbutaline, and increased the mRNA expression of β_2 receptors in type II cells (Isohama et al. 1997).

Beta-adrenergic drugs

Beta-adrenergic drugs stimulate adenylcyclase and inhibit phosphodiesterases, thereby increasing the amount of intracellular cAMP, which in turn increases the production (Lawson et al. 1978) and secretion of surfactant. cAMP stimulates the synthesis of disaturated phospholipids and SP-A; in addition, it mediates the effect of a number of hormones.

Thyroid hormones

Thyroxine (T_4) increases surfactant production and lung maturation. Infants who develop RDS have lower cord blood levels of T_4 than those who do not. T_4 does not easily cross the placenta, but triiodothyronine (T_3) given to pregnant rats is associated with an increase in T_3 in the fetal serum. T_3 increases the type II cell receptors' response to fibroblast pneumocyte factor, which is necessary for appropriate surfactant production. TRH, unlike T_4 and T_3 , readily crosses the placenta; it increases the amount of surfactant phospholipid. The effects of TRH are not entirely mediated by thyroid hormone. TRH stimulates prolactin production and functions as a neurotransmitter in the central nervous system.

Prolactin

Prolactin levels are lower in infants who develop RDS than in those who do not; they are also lower in immature than in mature infants and lower in males than in females (Dhanireddy et al. 1983). The effect of prolactin both in vivo and in cultured lung systems, however, is variable and the role of prolactin in surfactant production regulation remains speculative.

Epidermal growth factor

EGF may be important in the development of the pulmonary epithelium. Infusion of this substance into lambs prevents the development of hyaline membrane disease (Catterton et al. 1979) and increases lung distensibility. There is a reduced amount of SP-A in the offspring of rats with EGF autoantibodies (Raaberg et al. 1995). Müllerian-inhibiting substance inhibits lung maturation by blocking phosphorylation of EGF receptors (Catlin et al. 1991); this may be an explanation for the higher incidence of RDS in males. In non-human primate fetuses delivered at 78% of term, in utero treatment with EGF resulted in higher SP-A levels and L:S ratios in treated than in untreated fetuses (Goetzman et al. 1994).

Fibroblast pneumocyte factor

Alveolar cells need the presence of fibroblasts and their pneumocyte factor to produce surfactant (Smith 1979). Glucocorticoids act on the fetal lung fibroblasts to induce the production of fibroblast pneumocyte factor, which in turn stimulates rapid surfactant synthesis by the alveolar type II cell.

Insulin

Insulin delays the maturation of alveolar type II cells and decreases the proportion of saturated PC (Gross et al. 1980). In addition, infants of diabetic mothers have delayed appearance of PG (Ojomo and Coustan 1990). Hyperglycaemia also plays a role in the delay in lung maturation seen in these babies (Gewolb et al. 1985). Insulin inhibits SP-A gene expression (Miakotina et al. 2002).

Testosterone

Premature male infants are more prone to RDS than are similarly immature female infants (Perelman et al. 1986). Male lungs are approximately 1 week more immature as determined by the disaturated PC content. These differences may be due to inhibition of surfactant production in males by androgens (Torday 1985); lipid concentration in the lung appears to be at least partly directly or indirectly regulated by androgens (Ojeda et al. 1997). In addition, androgens delay lung maturation through their action on lung fibroblasts (Provost et al. 2002).

Surfactant physical properties and functions

Surfactant prevents atelectasis and thus reduces the work of breathing. This is achieved by reduction of surface tension and by surfactant becoming a 'solid' monolayer, promoting stability of the alveoli, in expiration. Surfactant also prevents the transudation of fluid: in conditions of high surface tension, fluid is sucked into the alveolar spaces from the capillaries.

The presence of an insoluble surface film capable of maintaining a very low surface tension (or high surface pressure) in the air spaces was first inferred by Pattle (1955). A small bubble will normally diminish in size and disappear; the smaller it becomes, the more rapidly its diameter decreases. This follows from the relationship described by the Laplace equation:

$$P = 2\gamma/r$$

where P = internal pressure, γ = surface tension and r = radius, that is, the pressure difference across the bubble's wall is given by twice the tension in the wall divided by the radius. Thus, in the presence of a high surface tension and small radius, the high pressure difference causes gas to diffuse from the bubble into the

surrounding liquid. In the lung, however, the presence of an insoluble surface film means that the surface tension is reduced as the radius decreases.

The contribution of surface tension to the pressure volume behaviour of the lung was demonstrated by von Neergaard (1929), who showed that lungs inflated with saline have a higher compliance than if filled with air. Saline abolishes the surface tension forces, which are an important component of the static recoil force of the lung.

Surfactant lowers surface tension by forming an insoluble surface film. This opposes the surface tension of the underlying liquid by exerting surface pressure. The surface properties of surfactant result from its composition, that is, molecules with both a hydrophobic and hydrophilic chain. When forming a film on water, the polar group is attracted to the water, whereas the non-polar group is turned towards the gas phase. DPPC is a symmetrical molecule and the two straight hydrophobic fatty acid chains allow close packing of the monolayer. Compression of such a monolayer results in it being changed from a liquid to a condensed gel or solid state (Clements 1977; Morley and Bangham 1981); this is because the transition temperature of the refined mixture rises to above 37°C, so that in vivo the refined monolayer may be solid (Clements 1977). In RDS, the PC is relatively unsaturated and of lower quantity than in the mature species. This means an unstable monolayer is formed on compression in expiration, which buckles and does not reduce surface tension effectively. Even when the monolayer has been refined, there is so little DPPC available the alveoli are of small size. Thus, infants with RDS have a low FRC and an increased work of breathing.

Inhibition of surface activity of surfactant by proteins

The alveolar surfactant system may be altered by an inhibitory effect of proteins leaked from the intravascular or interstitial space, owing to an increased permeability of the capillary endothelial and/or alveolar-epithelial barrier (Seeger et al. 1985). In RDS, the alveolar capillary membrane permeability is increased, and the hyaline membranes are a massive aggregation of fibrin. In addition, proteinaceous material may be inhaled, for example as in meconium aspiration syndrome. There is a marked rank order of potency of proteins in interfering with surfactant function – fibrin monomer > fibrinogen > albumin > elastin > IgG > IgM – such that fibrin has 50 times greater effectiveness than albumin. Once the proteins are present in the surface monolayer, they inhibit the ability of the compressed surfactant to lower surface tension. The leakage of protein on to the alveolar surface, at least in premature rabbits, can be inhibited by surfactant treatment and treatment with antenatal steroids or thyrotrophin-releasing hormone. In other conditions, such as meconium aspiration syndrome, the inhibitory effect of the proteins can be overcome by increasing the dose of surfactant. Exogenous surfactants differ with regard to their inhibition by proteins; calf lung surfactant extract and Alveofact are only moderately inhibited by fibrinogen (Barr et al. 1975). KL₄ surfactant, which has a synthetic peptide in lieu of SP-B, resists inhibition to serum proteins more than a natural surfactant (beractant) (Manalo et al. 1996).

Assessment of surfactant maturity

The fluid which is secreted by the fetal lung moves out into the amniotic fluid, carrying surfactant with it. As the lung matures, so the composition of the surfactant in the amniotic fluid changes. The

proportion of surfactant (lecithin) in the amniotic fluid can be compared with that of sphingomyelin (L:S ratio). An L:S ratio greater than 2.0 is usually associated with lung maturity and in 95% of cases will predict the absence of RDS. A mature L:S ratio, however, can be associated with RDS in the infants of diabetic mothers or in those with rhesus disease; in these cases, the abnormality is deficiency of PG rather than a lack of DPPC. Relating the amniotic fluid surfactant to the albumin level provides a more reliable predictor of the absence of RDS in infants of diabetic mothers than assessing the amount of DPPC (Tanasijevic et al. 1996). Unfortunately, an L:S ratio <2.0 predicts RDS with an accuracy of only 54%. The lower the L:S ratio, the more likely the baby is to develop RDS: 21% of babies with an L:S ratio of 1.5–2.0 are affected, compared with 80% with an L:S ratio below 1.5.

Identification of PG in the amniotic fluid is helpful, as babies with PG rarely develop RDS. A combination of a low L:S ratio with absence of PG from amniotic fluid samples obtained within 3 days of delivery is a better predictor of the duration of respiratory support than is either gestational age or birthweight, but only in pregnancies not complicated by premature rupture of the membranes (Harper

and Lorentz 1993). In diabetic pregnancies, the presence of PG correlated to an L:S ratio of >3.0 and a lamellar body count of at least 50 000 (Ghidini et al. 2002).

The L:S ratio can also be assessed in fluid from the pharynx (Barr et al. 1975; Hill 1976; Weller et al. 1976) or stomach (Motoyama et al. 1976). This can give retrospective demonstration that a baby had mature lungs at birth or provide further documentation on the course of a baby's illness (Kanto et al. 1976).

The level of serum SP-A in the first 24 hours has been shown to increase with advancing gestational age and differs significantly between infants with and without RDS (Kaneko et al. 2001). SP-A can also be measured in cord blood using an enzyme-linked immunosorbent assay system, so has been suggested to be a useful serum marker to predict the development of RDS (Kaneko et al. 2001). Tests of surfactant maturity, however, are now rarely employed, as many clinicians have the policy of giving exogenous surfactant very soon after birth to all infants born below a certain gestational age, because of the proven efficacy of prophylactic surfactant administration. Such tests may, however, be useful in developing countries (Denavit-Saubié et al. 1978).

Part 2: Acute respiratory disease

Anne Greenough Anthony D Milner

Respiratory distress syndrome

Respiratory distress syndrome (RDS), in non-intubated babies who have not received exogenous surfactant therapy or been exposed to antenatal corticosteroids, is characterised by a respiratory rate >60/min, dyspnoea (intercostal, subcostal indrawing, sternal retraction) with a predominantly diaphragmatic breathing pattern and characteristic expiratory grunt, all presenting within 4–6 hours of delivery. Oxygen administration is required to prevent cyanosis and there is a reticulogranular chest X-ray (CXR) appearance as a result of widespread atelectasis. Nowadays, that presentation is very unusual;

antenatal corticosteroids are routinely given and very prematurely born babies are intubated and given surfactant usually within the first hour after birth. The diagnosis in such babies then is based on their premature birth and CXR appearance. Pathophysiologically, the condition is characterised by non-compliant (stiff) lungs, which contain less surfactant than normal and become atelectatic at end-expiration. Histologically, hyaline membranes line the terminal airways. These membranes give the condition its alternative name, hyaline membrane disease (HMD), which, to be semantically correct, should be used only in the presence of histological confirmation; thus, the term RDS is preferred.

Incidence

In the modern era of neonatal intensive care, approximately 1% of infants develop RDS (Rubatelli et al. 1998).

Aetiology

RDS results from immaturity of the lungs, particularly the surfactant-synthesising systems. Various factors contribute to the immaturity and others interact with it to increase or decrease the incidence of the disorder.

Predisposing factors

Prematurity

The risk of RDS is inversely proportional to gestational age: 50% of babies less than 30 weeks of gestational age, as compared with 2% of those between 35 and 36 weeks, develop RDS (Rubatelli et al. 1998). RDS is almost invariable in infants of less than 28 weeks of gestation, but it does remain a significant problem up to 34 weeks' gestation (Lewis et al. 1996). The maturation of surfactant synthesis is a mirror image of the incidence of RDS at different gestations. Some of the dyspnoea and hypoxaemia in very preterm babies is due to their immature lung structure, with increased connective tissue and poorly developed alveoli. Other factors make the preterm neonate inherently susceptible to RDS. Their lung epithelia are more leaky than those of a baby born at term, increasing the likelihood of protein passing on to the alveolar surface, where it will inhibit surfactant function (see below). They are more prone to asphyxia, hypoxia, hypotension and hypothermia, all of which are likely to impair surfactant synthesis or increase alveolar capillary leakiness.

Gender

Boys are much more likely to develop RDS than girls, with a male-to-female ratio of 1.7:1, and are more likely to die from the disease (Farrell and Avery 1975). In male fetuses, the delayed maturation of the lecithin-to-sphingomyelin (L:S) ratio and late appearance of phosphatidylglycerol (PG) (Fleisher et al. 1985) are androgen-induced (Kotas and Avery 1971; Torday 1992).

Race

Black babies have a lower incidence of RDS – 60–70% of that of white babies of the same gestational age (Hulsey et al. 1993). This is evident even in very immature babies: in one series only 40% of African infants <32 weeks' gestational age developed RDS, compared with 75% of Caucasian infants (Kavvadia and Greenough 1998). No black baby with an L:S ratio >1.2 developed RDS, but white babies did develop the disease at those low ratios (Richardson and Torday 1994). Allelic variation in the surfactant protein A gene has been reported between American whites and Nigerian blacks (Rishi et al. 1992).

Caesarean section

Caesarean section carried out before the mother went into labour was reported to increase the risk of her baby developing RDS (Fedrick and Butler 1970; Usher et al. 1971), although this was not a consistent finding. Data from infants born at gestations above 32–34 weeks confirm the association of caesarean section before labour with both RDS and transient tachypnoea of the newborn (TTN) (Annibale et al. 1995; Morrison et al. 1995). The timing of the caesarean section is also important: the need for mechanical ventilation is 120 times greater after elective caesarean section at 37–38 weeks as compared with 39–41 weeks in babies with

surfactant deficiency (Madar et al. 1999). Review of 24 077 repeat caesarean deliveries at term demonstrated that births at 37 and 38 weeks compared with 39 weeks were associated with an increased risk of a composite outcome of neonatal death, respiratory complications, hypoglycaemia, newborn sepsis and admission to the neonatal unit (Tita et al. 2009). A review of nine studies comparing the outcome by mode of delivery of at or near-term infants demonstrated that all studies reported elective caesarean section was associated with an excess of respiratory morbidities with an average increased risk of two- to threefold (Hansen et al. 2007).

Birth depression

Babies who are depressed at birth are at increased risk of RDS. The incidence of RDS in babies less than 32 weeks of gestation was 54% in those with an Apgar <4 compared with 42% in babies with Apgars >4 ($p < 0.005$) (Beeby et al. 1994). During fetal asphyxia, lung perfusion falls, resulting in ischaemic damage to pulmonary capillaries. When the fetus recovers from the acute asphyxia, pulmonary hyperperfusion occurs and, if delivery occurs shortly afterwards, a protein-rich fluid leaks out of the damaged pulmonary capillaries. This leakage of proteins inhibits surfactant activity on the alveolar surface (Ikegami 1994). The protein leak can be prevented by exogenous surfactant (Ikegami et al. 1992), but in babies who respond poorly to surfactant administration, this benefit is probably overwhelmed by a large alveolar protein leak (Kobayashi et al. 1991). The surfactant protein (SP)-A (p. 460) is of specific benefit in minimising the inhibitory effect of protein on either endogenous or exogenous surfactant (Yukitake et al. 1995). One of the beneficial effects of antenatal steroids (p. 462) is that they reduce this capillary leakiness (Ikegami et al. 1987). The association between asphyxia and RDS is also influenced by hypoxia and acidaemia, predisposing to pulmonary hypertension and hypoperfusion with a right-to-left shunt (p. 498) and reducing surfactant synthesis by inhibiting the synthetic enzymes. RDS following birth depression blends into a spectrum with acute RDS (ARDS).

Maternal diabetes

Fetuses of diabetic mothers have abnormal surfactant synthesis, in particular a delay in the appearance of PG (Ojomo and Coustan 1990). Insulin delays the maturation of alveolar type II cells and decreases the proportion of saturated phosphatidylcholine in the surfactant (Gross et al. 1980). There are decreased levels of SP-A in amniotic fluid from diabetic pregnancies as compared with fluid from non-diabetic women (Snyder and Mendelson 1987). In cultured human lung tissue, insulin inhibits accumulation of SP-A and its mRNA (Snyder and Mendelson 1987; Dekowski and Snyder 1992). The incidence of RDS in infants of diabetic mothers (IDM) is increased by elective caesarean section before labour at 36–37 weeks. Improvements in maternal diabetic control during pregnancy have now facilitated delay in delivery until the 39th–40th week of gestation and RDS now occurs in fewer than 1% of patients (Kjos et al. 1990), even though in some the surfactant pattern at amniocentesis remains immature (Ojomo and Coustan 1990).

Hypothyroidism

Thyroid activity is important in the prenatal development of the surfactant system (p. 459). Preterm babies who develop RDS have lower levels of thyroid hormones in their cord blood than controls (Cuestas et al. 1976; Dhanireddy et al. 1983). The postnatal nadir in serum thyroxine concentration (seen in preterm infants) is very low in neonates with RDS (Vulsma and Kok 1996). Most term

babies with congenital hypothyroidism detected by screening do not develop RDS, but some cases do occur (Cohen et al. 1991).

Genetic predisposition

There are reports of families in which several relatively mature babies have developed RDS. At preterm gestations, if a woman has one baby with RDS, the relative risk of RDS in a subsequent low-birthweight (LBW) baby may be increased threefold (Nagourney et al. 1996). SP-B deficiency results in lethal respiratory failure (Nogee et al. 1994), which is associated with histopathological features of congenital alveolar proteinosis (Nogee et al. 1993). This abnormality has been described in families (Nogee et al. 1994) and the inheritance is autosomal recessive. Partial deficiency of SP-B, which may be compatible with survival, has been reported (Cole et al. 2000). Polymorphisms in intron 4 of the SP-B gene have been found to modify the course of RDS independently, as indicated by the frequency of severe RDS and the occurrence of bronchopulmonary dysplasia (BPD) (Makri et al. 2002). Specific alleles of the SP-A and SP-B genes associate interactively with susceptibility to RDS and dominant mutations of SP-C associate with BPD (Hallman and Haataja 2003).

Twins

The second twin is more likely to develop RDS (Hacking et al. 2001), although this is not a consistent finding and others have reported no difference between twins and singletons (Winn et al. 1992). There is similarity of L:S ratios in twins, which is greater in monozygotic than dizygotic pairs (Leslie et al. 1991).

Hypothermia

Surfactant function is defective in cold babies and the concomitant hypoxia and acidaemia impair surfactant synthesis (Merritt and Farrell 1976). In addition, below 34°C, even in the presence of adequate amounts of PG, dipalmitoyl phosphatidylcholine (DPPC) cannot spread to form an adequately functioning monolayer. Hypothermia in animals induces pulmonary hypertension and a fall in P_{aO_2} (Will et al. 1978); similar mechanisms may occur in neonates. Coagulation disorders are more common in hypothermic infants.

Nutrition

In animal studies, maternal malnutrition compromises fetal surfactant synthesis as well as lung growth (Lin and Lechner 1991). Postnatally, although calorie deprivation does not appear to be important (Farrell 1986), specific deficiencies of fatty acids or inositol may be relevant (Hallman et al. 1987). Inositol supplementation in babies with RDS improves outcome (Hallman et al. 1992), reducing the risk of BPD or death, and severe retinopathy of prematurity (ROP) (Howlett and Ohlsson 2003).

Intrauterine growth retardation

An appropriately grown infant of 28 weeks' gestational age is much more likely to develop severe RDS than a growth-retarded 32-week-gestation infant of similar birthweight (Piper et al. 1996). Severely growth-retarded infants, however, have a higher incidence of RDS and it is more severe (Thompson et al. 1992; Piper et al. 1996).

Haemolytic disease of the newborn

The development of pulmonary maturity may be delayed in severely affected infants with haemolytic disease of the newborn with or without hydrops (Quinlan et al. 1984). A possible mechanism is the increased levels of insulin due to beta-islet cell hypertrophy, as occurs in IDM (Ch. 22). The presence of heart failure with

proteinaceous pulmonary oedema fluid aggravates any pre-existing surfactant deficiency due to prematurity.

Time of cord clamping

Preterm neonates who had undergone early cord clamping and had a low red cell mass, particularly when combined with some degree of birth depression, were more prone to develop RDS. As a consequence, it was recommended that following preterm delivery the cord should not be clamped until 1–2 minutes after delivery (Usher et al. 1975). A small prospective study of babies less than 33 weeks' gestation showed that a 30-second delay in cord clamping had no effect on mortality, but that the late-clamped babies were easier to ventilate in the first few days and required fewer blood transfusions (Kinmond et al. 1993).

Factors with equivocal effects on the incidence of RDS

Maternal hypertension

Some have reported a higher incidence of RDS in preterm infants of hypertensive mothers (Troche et al. 1995), perhaps due to delivery by caesarean section before labour. In contrast, no effect of pre-eclampsia with or without growth retardation was demonstrated on the results of lung maturity tests, neonatal morbidity including RDS or mortality (Schiff et al. 1993; Friedman et al. 1995). In another study, RDS occurred in 15% of infants of mothers with hypertensive pre-eclampsia but in 38% of non-hypertensive controls of similar weight and gestation (Shah et al. 1995).

Prolonged rupture of membranes

There is no consensus regarding the impact of prolonged rupture of membranes (Hallak and Bottoms 1993; Wolf et al. 1993). An apparent benefit may be explained by greater use of antenatal steroids in affected pregnancies (Thompson and Greenough 1993).

Factors reducing the incidence of RDS (see prevention of RDS, pp. 473–475)

Maternal addiction

Maternal narcotic addiction and smoking (Lieberman et al. 1992) reduce the incidence of RDS. Heroin can mature the surfactant-synthesising systems. The effect of cocaine is unclear (Beeram et al. 1995; Hanlon-Lundberg et al. 1996), although in animal models it induces surfactant synthesis (Sosenko 1993).

Pathology

The initial histological finding (Gandy et al. 1970) in non-surfactant-treated infants with RDS is alveolar epithelial cell necrosis developing within half an hour of birth. The epithelial cells become detached from the basement membrane and small patches of hyaline membranes form on the denuded areas. At the same time, there is diffuse interstitial oedema. The lymphatics are dilated by the delayed clearance of fetal lung fluid and the capillaries next to the membranes have a sludged appearance. There are very few osmiophilic granules in the type II cells, which in places contain vacuoles, suggesting that all the lamellar bodies have been discharged. In the early stages, all these changes are rather patchy, but, by 24 hours, more extensive generalised membrane formation in the transitional ducts and respiratory bronchioles occurs. Hyaline membranes line the overdistended terminal and respiratory bronchioles (Fig. 27.11), particularly where the airways branch, and may

Fig. 27.11 Histology of respiratory distress syndrome, showing pink-staining hyaline membranes lining a terminal bronchiole with surrounding atelectasis.

extend into the putative alveolar ducts. The most distal component of the respiratory unit, the terminal sacs, although collapsed, are not lined by membranes. The hyaline membranes are eosinophilic on staining with haematoxylin and eosin, and contain nuclear debris from necrotic pneumocytes. Occasionally, when the infant has hyperbilirubinaemia, the membranes are yellow, reflecting the presence of unconjugated bilirubin. The hyaline membranes are formed by coagulation of plasma proteins, which have leaked on to the lung surface through damaged capillaries and epithelial cells; the fibrillary component of the membranes is derived from exuded fibrin. After 24 hours, a few inflammatory cells appear within the airway lumen; macrophages are usually the most prominent cell, although some polymorphs may also be present. Ingestion of the membrane by macrophages takes place over the next 2 or 3 days as the membrane separates. Macrophages are also present beneath the membrane within the interstitium, which is usually oedematous and where there may be a mild fibroblastic response. Epithelial regeneration is detectable after 48 hours, usually beneath the separating membranes. Cuboidal cells from the unaffected transitional ducts become large and mitotic; they flatten out and spread beneath the hyaline membranes. Other cells produce lamellar bodies. Many of these reparative cells form abnormally thick epithelial squames and, with damaged capillaries, can present a considerable barrier to efficient gas exchange. During this stage of repair, surfactant can be detected in increasing quantities on the alveolar surface (Gandy et al. 1970). By 7 days of age, the hyaline membranes will have disappeared in an infant with uncomplicated RDS. In ventilated babies, however, the healing process is markedly altered and delayed. There is a hyperplastic healing process, with massive shedding of bronchiolar epithelial cells and type II pneumocytes. Hyaline membranes remain prominent. The terminal airways may be plugged with secretions and there is progressive scarring and fibrosis of the alveoli and airways, leading to the picture of BPD (p. 552).

Pathophysiology

Lung function

The lungs are stiff, with compliance values of approximately 0.3–0.5 ml/cmH₂O/kg, when the disease is at its worst (Bhutani et al. 1988a) (Table 27.4). As surfactant begins to appear, the compliance improves and has usually returned to values of 1–2 ml/cmH₂O/kg

Table 27.4 Values for lung mechanics in respiratory distress syndrome

Tidal volume (V_T)	4–6 ml/kg
Minute volume (V_E)	250–400 ml/kg/min
Alveolar ventilation (V_A)	50–90 ml/kg/min
Physiological dead space (V_D/V_T)	60–75%
Functional residual capacity (FRC)	3–20 ml/kg
Crying vital capacity	20–30 ml
Dynamic compliance (C_L)	0.0003–0.0005 l/cmH ₂ O/kg
Inspiratory resistance ($R_{aw\text{ Insp}}$)	55–95 cmH ₂ O/l/s
Expiratory resistance ($R_{aw\text{ Exp}}$)	140–200 cmH ₂ O/l/s
Work of breathing	800–3000 g.cm/min/kg
From various sources quoted in the text.	

(Migdal et al. 1987) by 6–7 days of age. In severe disease, the functional residual capacity (FRC) may be as low as 3 ml/kg (Dimitriou and Greenough 1995a), whereas the FRC is at a normal level of 25–30 ml/kg in recovering babies (Richardson et al. 1986). Babies with RDS have a low tidal volume and a large physiological dead space. Minute ventilation, however, may be increased by an elevated respiratory rate in an attempt to sustain alveolar ventilation, but this is usually unsuccessful, resulting in alveolar underventilation and carbon dioxide retention. Pressure–volume loops on lungs excised at postmortem from babies dying of HMD have a characteristic pattern (Fig. 27.12). During inflation, the volume change for a given increase in pressure is very small, and, during deflation, the change in volume follows a track almost similar to that seen during inflation, whereas, in the normal lung, air is retained until low pressures are reached (hysteresis). As the pressure drops to zero, very little or no air is retained within the surfactant-less alveoli, corresponding to the very small FRC measured in vivo. Inspiratory resistance is usually normal in RDS (Hjalmarson and Olsson 1974) but expiratory resistance is increased, probably as a result of the closure of the airway prior to the expiratory grunt (Strang 1977). It is also increased by the presence of an endotracheal tube (ETT) (Edberg et al. 1991). An inevitable sequela of the abnormal lung mechanics is that the work of breathing is increased in neonates with RDS to twice that seen in those without RDS (Hjalmarson and Olsson 1974; McCann et al. 1987).

The time constant gives a measure of the time available for gas to leave the lung during expiration, which is normally accepted to take three time constants. The time constant is the compliance (l/cmH₂O) multiplied by the airways resistance (in cmH₂O/l/s). It is very short in neonates with severe RDS:

$$\begin{array}{lll} 0.001 \text{ l/cmH}_2\text{O} \times 100 \text{ cmH}_2\text{O/l/s} = & 0.1 \text{ seconds} \\ \text{(compliance)} & \text{(resistance)} & \text{(time constant)} \end{array}$$

In babies with less stiff lungs, however, the time constant will be longer, and if the baby breathes rapidly (at 80/min), this will result in gas being retained in the lungs when the next inspiration starts (Strang 1977). Clinical studies (South and Morley 1986b; Hird and Greenough 1991) have shown the respiratory rate of infants with RDS to be about 80–90/min, with an average inspiratory time of 0.25–0.35 seconds. This pattern of respiration may be adopted so

Fig. 27.12 Pressure–volume loops in excised lungs of neonates dying with and without hyaline membrane disease (HMD). In HMD, the deflation curve closely follows the inflation curve and little air is retained at zero pressure. In normal lungs, much more air is retained on the deflation limb of the loop (the phenomenon of hysteresis). (Reproduced from *Gribetz et al. (1959).*)

that the neonate retains gas within the lungs and some level of FRC is maintained.

A characteristic feature of RDS is the expiratory grunt. This is the result of the baby attempting to sustain an FRC by delaying the escape of air from the lungs during expiration. The baby tries to do this in two ways: firstly, during expiration, the diaphragm continues to contract, trying to delay or brake the reduction in thoracic volume and thus retain gas within the alveoli (*Davis and Bureau 1987*); secondly, by contracting the constrictor muscles of the larynx, an attempt is made to close the upper airway, as in the Valsalva manoeuvre. Since the abdominal muscles contract at the same time as the laryngeal muscles relax, there is an explosive exhalation of air, which is the characteristic ‘grunt’. Bypassing this laryngeal component of expiratory braking by putting an ETT through the cords results in a fall in the P_{aO_2} in babies with RDS (*Harrison et al. 1968*).

Surfactant

The preterm baby is born with poor reserves of surfactant (p. 459). Most babies, however, have some present in the first few hours after birth. The deterioration seen in babies with non-surfactant-treated RDS is due in part to the disappearance of these small quantities of surfactant, compounded by fatigue as the neonate struggles to sustain ventilation in stiff, surfactant-deficient lungs. The disappearance of surfactant is primarily due to the inhibitory effect of proteins on surfactant (see above) (*Ikegami et al. 1983*), which leak on to the alveolar surface in the early oedematous stage of lung damage. The deleterious effect of hypoxia and acidaemia on surfactant synthesis (p. 462) may also play a part, but patency of the ductus is not relevant (*Alpan et al. 1989*). The levels of surfactant proteins are also low in the first few hours in babies with RDS and rise as the babies recover. The lungs remain non-compliant and atelectatic

until surfactant begins to reappear from 36 to 48 hours of age, as demonstrated by measurement of L:S ratios of pharyngeal aspirates (*Kanto et al. 1976*).

Pulmonary hypertension

Pulmonary artery pressure (PAP) remains high throughout the first week and even longer in some cases of RDS (*Evans and Archer 1991b; Skinner et al. 1992a*). The more severe the RDS, the higher the PAP, which may remain close to systemic levels in fatal cases (*Walther et al. 1992*). At least during systole, PAP can be higher than systemic pressure, at which time there is likely to be right-to-left ductal shunting. In diastole, the systemic pressure is likely to be higher than the pulmonary pressure and the overall effect is bidirectional ductal shunting, and this is frequently detected echocardiographically in RDS (*Evans and Archer 1991a, b; Skinner et al. 1992b*).

Mechanisms of hypoxia: right-to-left shunt with ventilation–perfusion imbalance

Hypoxaemia in RDS is due to a large right-to-left shunt. There are four main sites of right-to-left shunts:

1. Obligatory shunts present due to drainage of the veins of the myocardium directly into the left side of the heart and anastomoses between the bronchial and pulmonary circulation. These are small and of no haemodynamic or clinical significance.
2. Shunting through the foramen ovale occurs if right atrial pressure is higher than left atrial pressure. Interatrial right-to-left shunting is rare in neonates with RDS (*Stahlman et al. 1972; Evans and Iyer 1994*).
3. Shunting through a patent ductus arteriosus (PDA): the ductus arteriosus is patent in most babies with RDS during the first 48–72 hours (*Dudell and Gersony 1984; Rigby et al. 1984*). If the PAP exceeds the aortic pressure, there will be a significant right-to-left shunt. Right-to-left shunts at ductal level are common in persistent pulmonary hypertension of the newborn (PPHN; p. 495) but in uncomplicated RDS are small and constitute <10% of the total right-to-left shunt (*Seppänen et al. 1994*). Right-to-left ductal shunting means that blood taken from an umbilical artery catheter (UAC) can have a much lower P_{aO_2} than blood passing up the carotid arteries to the eyes. Colour Doppler studies in babies with RDS have demonstrated that intravascular shunting at the ductal or foramen ovale level is relatively unusual and the shunts through these channels are predominantly bidirectional or left-to-right in the first few days after birth. This has little effect on blood gas values, but increases the cardiac output and the load on the right ventricle (*Evans and Archer 1991b; Evans and Iyer 1994; Seppänen et al. 1994*).
4. The true intrapulmonary right-to-left shunt, when pulmonary capillary blood passes through the lung without coming into contact with a ventilated alveolus.

The combination of the above is the true right-to-left shunt. There is another right-to-left shunt which contributes to the total shunt or venous admixture seen in babies with RDS, and it is the result of pulmonary blood flow passing partially ventilated alveoli, that is, ventilation–perfusion imbalance. This large component of the right-to-left shunt in RDS can be eliminated by giving the baby 100% oxygen to breathe for 15 minutes (the hyperoxia or nitrogen washout test). This eliminates shunting resulting from partially

oxygenated alveoli, and a shunt calculated at the end of a period breathing 100% oxygen is the true shunt outlined above. In most babies with RDS, the majority of the right-to-left shunt is the fourth component of the true shunt plus the shunt from ventilation-perfusion imbalance.

Carbon dioxide retention

The increased P_{aCO_2} in RDS is due to hypoventilation secondary to atelectasis, decreased tidal volume and increased dead space. Ventilation is also non-homogeneous, so whereas end-tidal P_{ACO_2} is a good measure of P_{aCO_2} in patients with normal lungs, in babies with RDS there is a risk that measurement of P_{ACO_2} will seriously underestimate P_{aCO_2} . Since the mixed venous P_{CO_2} (normally 6.13 kPa, 46 mmHg) is usually only a fraction of a kilopascal above arterial or alveolar P_{CO_2} (normally 5.33 kPa, 40 mmHg), the right-to-left shunt has to be enormous before the admixture of venous blood significantly contributes to hypercapnia in RDS.

Prevention of respiratory distress syndrome

Prevention of prematurity

Tocolytic drugs to prevent preterm labour have proved disappointing (King et al. 1988; Leonardi and Hankins 1992), prolonging pregnancy for not more than 48 hours (Keirse 1995). Genital tract infection is associated with preterm labour, and in women with preterm rupture of the membranes (PROM) there is evidence that treatment with antibiotics reduces the prematurity rate (Gomez et al. 1995).

Antenatal steroid therapy

Not all steroids cross the placenta; cortisol is largely inactivated, but degradation is resisted by synthetic steroids such as betamethasone and dexamethasone. Antenatal administration of dexamethasone or betamethasone to pregnant women in preterm labour significantly reduces the incidence of RDS and neonatal death (Roberts and Dalziel 2010). Several other serious complications of prematurity, including germinal matrix/intraventricular haemorrhage (GMH/IVH) and necrotising enterocolitis (NEC), are also reduced (Ward 1994; Crowley 1995; Eriksson et al. 2009). No long-term adverse effects were demonstrated from a single course of antenatal corticosteroids (Dessens et al. 2000). In a population-based cohort of 79 395 infants, antenatal steroid therapy was found to be an independent risk factor for asthma between 36 and 72 months of age (odds ratio 1.23) (Pole et al. 2009), but antenatal exposure to a single course of betamethasone did not alter lung function or the prevalence of wheeze and asthma at age 30 (Dalziel et al. 2006). Follow-up of antenatally steroid-treated babies shows no excess of handicap compared with controls (MacArthur et al. 1981; Doyle et al. 1989).

Some of the beneficial effects of corticosteroids are the consequence of reducing the incidence and severity of RDS, whereas others represent the maturing effect of steroids on many body systems. The interaction with the benefits of postnatal exogenous surfactant therapy is of particular importance. The effects of antenatal steroids (Table 27.5) include inducing the enzymes for surfactant synthesis and the genes for the production of the surfactant proteins A, B, C and D (Mendelson et al. 1993), and improving the quality of the surfactant produced (Ueda et al. 1995). Glucocorticoids, such as dexamethasone, can cause substantial stimulation of SP-B gene expression to two to three times adult levels in fetal lung explants (Benson 1993). They mature the non-surfactant-producing

Table 27.5 Benefits of antenatal steroids

Improved Apgar scores	Gardner et al. (1995)
Maturation of lung structure	Bunton and Plopper (1984) Lanteri et al. (1994)
Initiation of surfactant protein synthesis	Mendelson et al. (1993)
Improved NO-mediated pulmonary venous relaxation	Zhou et al. (1996)
Reduced pulmonary capillary leakiness	Ikegami et al. (1997)
Interaction with postnatal exogenous surfactant therapy	p. 475
Increased resistance to high oxygen exposure	Frank (1992)
Better blood pressure in early neonatal period	Moise et al. (1995)
Higher neonatal white cell counts	Barak et al. (1992)
Less patent ductus arteriosus	Eronen et al. (1993); Ward (1994)
Less GMH/IVH	Crowley (1995); Garland et al. (1995)
Less NEC	Ward (1994)
NO, nitric oxide; GMH/IVH, germinal matrix/intraventricular haemorrhage; NEC, necrotising enterocolitis.	

tissues of the lung (Bunton and Plopper 1984; Lanteri et al. 1994); the septa become longer, thinner and less cellular, with larger air spaces and increased numbers of alveolar divisions. In addition, antenatal steroids increase antioxidant enzyme activity and reduce oxidative stress (Vento et al. 2009); the maximum effect was seen with steroids administered 2–4 days before delivery and females benefited more.

Timing of treatment

Results from randomised trials have demonstrated that the benefit is maximal in babies delivered between 24 and 168 hours after starting the maternal therapy (Crowley 1995). A smaller but useful benefit is also seen in women receiving less than 24 hours of therapy.

Number of courses

There are doubts about the safety of multiple courses of corticosteroids (Ikegami et al. 1997; French et al. 1999), which cannot be recommended as routine treatment. Repeated courses of therapy may suppress the maternal and fetal hypothalamic-pituitary-adrenal axis (Ballard et al. 1980), as well as increasing the risk of maternal hyperglycaemia and infection. Neonatal Cushing syndrome has been reported after repeated antenatal courses of steroids (Bradley et al. 1994). Steroids, however, may depress the neonatal adrenal gland when used in conventional doses (Kari et al. 1996). Evidence from eight randomised controlled trials in animal models highlighted that, although repeated doses of antenatal corticosteroids have beneficial effects in terms of lung function, they can have adverse effects on brain function and fetal growth (Aghajafari et al.

2002). Similar effects have been seen in infants following repeated courses. In one study (Wapner et al. 2006), infants exposed to more than four courses had significant weight reductions. In a large randomised study (Crowther et al. 2006), although repeated courses of steroids (weekly) reduced both the risk of RDS and need for supplementary oxygen and shortened the duration of mechanical ventilation, z scores for weight and head circumference were lower at hospital discharge. In another large randomised study (Murphy et al. 2008), infants exposed to repeated courses (fortnightly) had similar morbidity and mortality, but weighed less, were shorter and had a smaller head circumference (Murphy et al. 2008). Data regarding the efficacy of rescue steroids after only one standard administration are mixed. A single rescue course of antenatal corticosteroids before 33 weeks in women who had completed a single course before 30 weeks of gestation was associated with a lower rate of neonatal morbidity and significantly decreased RDS and surfactant use (Garite et al. 2009), but in another study the requirement for surfactant was increased in infants exposed to a single repeated dose of betamethasone (Peltoniemi et al. 2007). A single repeated dose of antenatal betamethasone given for imminent preterm birth at least 1 week after standard betamethasone treatment, however, was not shown to influence neurodevelopmental outcome and had no significant effect on growth at 2 years of age (Peltoniemi et al. 2009).

Gestational age

In the original study by Liggins and Howie (1972), the greatest benefit was seen at gestations of 30–34 weeks, with a much smaller, although statistically significant, benefit below 30 weeks. Crowley's meta-analysis (Crowley 1995) demonstrated a benefit in neonates less than 31 weeks, but evidence for benefit in babies of less than 28 weeks is less strong (Doyle et al. 1986; Garite et al. 1992).

Preterm rupture of membranes

Although there has been concern that, in PROM, antenatal steroids may increase risk of infection, with appropriate clinical surveillance this was not a problem in the studies reviewed by Crowley (1995); indeed, a beneficial effect of antenatal steroids in pregnancies complicated by PROM was demonstrated.

Maternal hypertension

Liggins and Howie (1972) reported that steroid-treated hypertensive women had a significantly increased stillbirth rate and perinatal mortality; as a consequence, such women were excluded from trials (Crowley 1995). Clinical experience and observational studies, however, suggest that steroids can be used safely in this situation (Lamont et al. 1983).

Diabetes

In the past, glucocorticoids were avoided in diabetic pregnancies because of their potential for causing hyperglycaemia; however, they should be given, as the insulin regimen can be altered during the brief period of hyperglycaemia. Steroids switch on the surfactant protein-synthesising systems in experimental diabetic rats (Moglia and Phelps 1996).

Twins

Multiple pregnancies have often been excluded from trials of antenatal corticosteroids.

Guidelines for antenatal steroid usage

Guidelines have been produced by the Royal College of Obstetricians and Gynaecologists (1996), the British Association of

Perinatal Medicine (Sweet et al. 2007), and the National Institutes of Health of the USA (NIH Consensus Panel Development 1995). Their recommendations include:

- Antenatal treatment with corticosteroids should be considered for all women at risk of preterm labour between 24 and 36 weeks. Treatment should consist of two doses of betamethasone given intramuscularly 24 hours apart or four doses of dexamethasone given 12 hours apart. Betamethasone, however, is now preferred, as in an observational study (Baud et al. 1999) it was associated with a lower risk of periventricular leukomalacia (PVL). In a non-randomised comparison, betamethasone compared with dexamethasone was associated with lower rates of RDS and BPD (Feldman et al. 2007).
- Treatment for less than 24 hours is associated with significant improvement in outcome; thus, corticosteroids should be given unless immediate delivery is anticipated.
- In the absence of chorioamnionitis, antenatal corticosteroids are recommended in pregnancies complicated by preterm PROM.
- Unless there is evidence that corticosteroids will have an adverse effect on the mother, they are also recommended in other complicated pregnancies.

Thyroid preparations

Thyroid hormones are involved in the induction of surfactant synthesis (Ballard 1984; Gonzales et al. 1986). There are reports of apparent success with intra-amniotic therapy (Romaguera et al. 1993), as thyroid hormones and thyroid-stimulating hormone do not cross the placenta, but most researchers have studied the administration of thyrotrophin-releasing hormone (TRH) to the mother, usually in combination with dexamethasone. There is a consistent synergism between TRH and steroids in animal studies (Moraga et al. 1994; Polk et al. 1995). Although the results of early clinical studies were promising, in the ACTOBAT study (ACTOBAT Study Group 1995), the TRH group suffered increased morbidity, as they delivered at significantly earlier gestations. Meta-analysis of the results of 11 trials, which included 4500 women, has demonstrated that prenatal administration of TRH in addition to corticosteroids did not reduce the risk of neonatal respiratory distress or BPD. Indeed, the data showed there were adverse effects: an increase in requirement for ventilation and more likelihood of having a low Apgar score at 5 minutes (Crowther et al. 2000). Antenatally administered TRH can also produce transient suppression of the pituitary–thyroid axis and transient complications in the mother, including nausea, vomiting and increased blood pressure (BP) (Gross and Moya 2001).

Other antenatal drugs

Various drugs have been used in animal experiments to mature the surfactant synthetic pathways. These include opiates, aminophylline (Karotkin et al. 1976) and ambroxol (Robertson 1981). Benefit from ambroxol has been reported (Wauer et al. 1992), but this is not a consistent finding (Dani et al. 1997). Some (Wyszogrodski et al. 1974) but not all (Fiascone et al. 1992) animal experiments suggest that antenatal beta-mimetics may improve neonatal lung function. Their effect in the human neonate appears to be small (Laros et al. 1991), although, in a randomised controlled trial (Eisler et al. 1999), infants whose mothers had received an infusion of terbutaline prior to elective delivery had significantly better lung function.

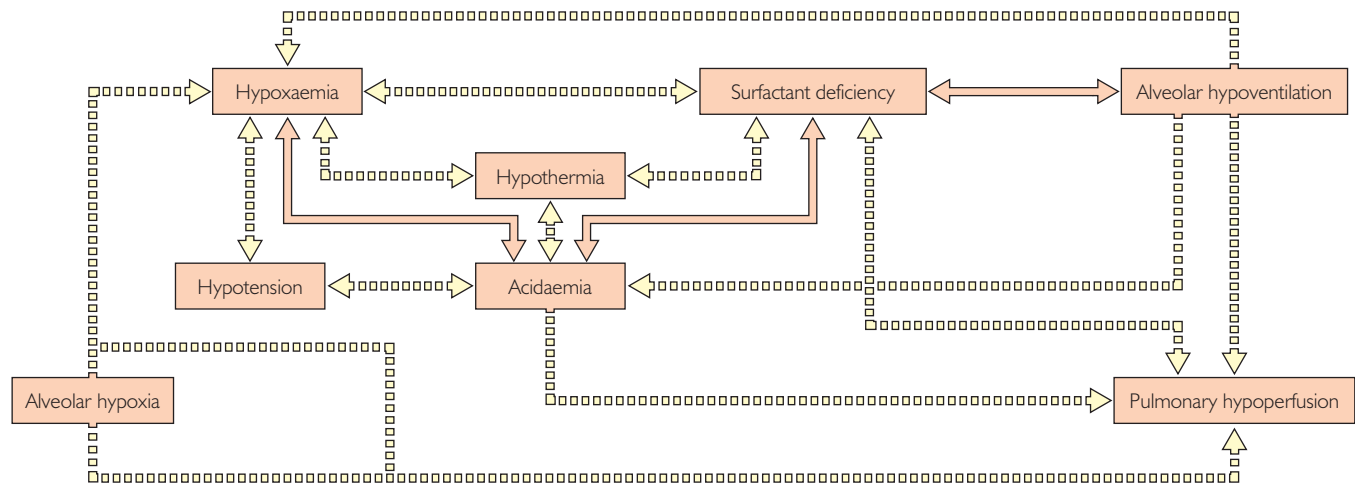

Fig. 27.13 Interrelationship of factors affecting surfactant and other components of lung function; solid lines indicate major effects. (Reproduced from Robertson (1992).)

Prevention of intrapartum asphyxia

Asphyxia worsens RDS and predisposes to pulmonary haemorrhage. If asphyxia is absent and the preterm neonate is presenting by the vertex, there is no need to proceed to caesarean section on a routine basis (Ahn et al. 1992), but if fetal compromise develops, delivery by caesarean section should be considered even at early gestations.

Prevention of postnatal asphyxia

It is important to prevent postnatal hypoxic damage to lung capillaries and minimise the risk of haemorrhagic pulmonary oedema, by rapidly establishing normal blood gases and normal pulmonary perfusion and ensuring maximum surfactant release from the type II pneumocytes by adequate expansion of the lungs. Inadequate ventilation leads to poor surfactant release, resulting in hypoxia and acidaemia, leading to a vicious cycle (Fig. 27.13). As a consequence, it had been argued that, unless a baby of <30 weeks of gestation is in excellent condition at 30 seconds of age, crying and vigorous, the baby should be actively resuscitated by intubation and intermittent positive-pressure ventilation (IPPV). The studies (Drew 1982; Robson and Hey 1982) which demonstrated such an approach, reducing morbidity and mortality from RDS, however, were performed before the modern era of neonatal intensive care and a less aggressive approach using continuous positive airway pressure (CPAP) rather than IPPV is now preferred in many centres (p. 231). Prevention of asphyxia, however, remains important, and appropriate resuscitation may require endotracheal intubation (Linder et al. 1999).

Avoiding drug depression

Many drugs given to the mother in preterm labour – including opiate analgesics and anaesthetic agents – can result in marked hypotonia and respiratory depression in the infant. In general, as well as using the specific opiate antagonist naloxone (except in infants of drug-addicted mothers, in whom naloxone will precipitate drug withdrawal signs), affected babies may require ventilation from birth until the drugs are excreted or metabolised.

Avoidance of maternal fluid overload

Excessive fluid administration to the mother in labour may result in neonatal hyponatraemia (Tarnow-Mordi et al. 1981).

Prophylactic surfactant

All trials of surfactant therapy have shown a reduction in oxygen requirements and the ventilator pressures required. Problems with the measurement techniques resulted in confusion regarding the effect of surfactant on compliance, as the early improvements may not be detected by dynamic compliance measurements. Surfactant also results in elevation of lung volume (Cotton et al. 1993), in association with increased oxygenation (Dimitriou et al. 1997).

A large number of studies have been carried out assessing the impact of prophylactic surfactant, i.e. administering surfactant within the first few minutes after birth. Many varieties of surfactant have been used (Table 27.6). Meta-analyses of the results have been performed (Soll 1996; Soll and Blanco 2009; Soll and Morley 2009) demonstrating positive effects of both synthetic and natural surfactants. Prophylactic use of natural surfactant results in a significant reduction in pneumothorax, mortality, and the combined outcome of mortality and BPD, but not BPD alone (Soll 2000a). In a randomised trial, Lucinactant, a synthetic surfactant containing a functional SP-B mimic that is leucine and lysine repeating units (KL4), was associated with significantly lower incidence of RDS at 24 hours than a non-protein-containing synthetic surfactant and lower RDS-related mortality at 14 days than either the non-protein-containing surfactant or a bovine-derived surfactant (Moya et al. 2005). In another study (Sinha et al. 2005), however, Lucinactant was not more effective and meta-analysis of the results of the two randomised trials does not demonstrate that Lucinactant was associated with significant benefits at 36 weeks' postmaturation age compared with an animal-derived surfactant (Pfister et al. 2007).

Meta-analyses of the results of trials comparing administering surfactant prophylactically or selectively, or early versus late, have demonstrated prophylactic/early administration is more effective. Prophylactic versus selective surfactant administration has been associated with a significant reduction in neonatal mortality, BPD/death and pneumothorax (Stevens et al. 2007) and early versus late administration a reduction in neonatal mortality and pneumothorax (Yost and Soll 2000). Early surfactant replacement with extubation to nasal CPAP (nCPAP), as compared with later, selective surfactant replacement and continued mechanical ventilation, was associated with an increased utilisation of exogenous surfactant replacement therapy (Stevens et al. 2007). In a subsequent trial (Sandri et al. 2010) prophylactic surfactant followed by extubation to nCPAP was not superior to early selective surfactant in terms of

Table 27.6 Surfactants which have been used in clinical studies

TYPE OF SURFACTANT	ANIMAL SOURCE	COMPOSITION (OR ADDITIVES IF ANIMAL-DERIVED)
Protein-containing animal surfactants		
Surfactant TA	Cow	DPPC, palmitic acid triglyceride
Survanta	Cow	Similar to Surfactant TA
Infasurf (CLSE)	Cow	
Curosurf	Pig	
BLES	Cow	
Alveofact SF-RI 1	Cow	
Human surfactant	Liquor amnii	
Artificial surfactant		
Non-protein surfactants		
ALEC (Pumactant)		70% DPPC, 30% PG
Exosurf		DPPC + tyloxapol and hexadecanol
Peptide-containing synthetic surfactants		
Venticute		DPPC, POPG, PA, rSP-C
Lucinactant		Synthetic SP-B analogue made of lysine-leucine (KL4)
DPPC, dipalmitoyl phosphatidylcholine; PG, phosphatidylglycerol; POPG, palmitoyloleoylphosphatidylglycerol; PA, palmitic acid; rSP-C, recombinant surfactant protein C.		

requirement for mechanical ventilation in the first 5 days after birth in infants born between 25 and 28 + 6 weeks' gestation. In a study of 1316 infants (SUPPORT study group 2010), infants randomised to intubation and surfactant treatment within 1 hour of birth compared with those randomised to CPAP in the delivery room had similar outcomes with respect to the primary outcome of death or BPD. Infants who received CPAP, however, less frequently required postnatal steroids ($p < 0.001$), required fewer days of mechanical ventilation ($p = 0.03$) and were more likely to be alive and free from the need for mechanical ventilation by day 7 ($p = 0.01$). Those results suggest that when nasal CPAP is used in the labour ward administration of surfactant can be delayed until the infant has displayed signs of respiratory distress.

Clinical features of respiratory distress syndrome

The diagnostic criteria for RDS were laid down before use of prophylactic surfactant. These comprised: a respiratory rate above 60/min; grunting expiration; indrawing of the sternum, intercostal

spaces and lower ribs during inspiration; and cyanosis without added oxygen (Rudolph and Smith 1960).

Natural history

The disease is present within the first 4 hours after birth. In the absence of treatment with exogenous surfactant, over the next 24–36 hours the baby tires, dyspnoea worsens and the baby becomes oedematous. As surfactant synthesis commences, the severity of the disease begins to abate from 36–48 hours of age, and this is associated with a spontaneous diuresis (Kavvadia et al. 1998).

Respiratory signs

The more mature baby with RDS may breathe at a fast respiratory rate, exceeding 100/min. This faster rate is more efficient in terms of work of breathing. Some babies may alternate a breathing pattern of shallow tachypnoea up to 100–120/min with one in which they breathe comparatively slowly (40–60/min) with marked recession and grunting. The slow-breathing baby often has episodes of apnoea, and this is a sign that respiration is beginning to fail (Davis and Bureau 1987). In addition to tachypnoea, there is marked intercostal and sternal recession, and flaring of the alae nasi. The main respiratory muscle is the diaphragm. In the presence of a compliant ribcage, diaphragmatic contraction results in a marked seesaw pattern, the chest moving inwards and the abdomen moving outwards during inspiration and vice versa on expiration. On auscultation there is a reduction in air entry. An expiratory grunt is a feature of most forms of neonatal respiratory disease and results from the baby trying to sustain FRC (p. 457). In uncomplicated RDS, these clinical features gradually return to normal by 7 days at the latest.

Cardiovascular signs

The heart rate in mild to moderate cases of RDS is 140–160/min and shows normal variability. In infants with severe RDS, the heart rate tends to be slower (120/min) with little beat-to-beat variation. The heart sounds are normal. Murmurs are not normally present; if heard in the first 24–48 hours, they suggest congenital heart disease or ischaemic myocardial injury and require further investigation. A murmur appearing after 3–4 days is usually due to a PDA. Heart failure is not a feature of RDS; if present, it suggests cardiac disease.

Neonates with RDS are often hypotensive and this is associated with a worse prognosis (Hallman et al. 1993). Hypotension is less common in babies who receive antenatal steroids (Moise et al. 1995). There are many causes for the hypotension, including hypoxia and acidaemia depressing the myocardium and reducing cardiac output, a low blood volume and high-pressure ventilation compromising venous return and reducing cardiac output. Hypotension predisposes to acidaemia, which increases pulmonary vascular resistance, GMH/IVH (Ch. 40.5), renal failure (Ch. 35.1) and NEC (Ch. 29.3). It is essential, therefore, to measure the BP and correct symptomatic hypotension.

Central nervous system

The preterm baby even without RDS is hypotonic, inactive and lies in the frog position, spending most of the day asleep. Abnormal neurological signs are often subtle (Ch. 40.1), but if present they are ominous, suggesting development of a GMH/IVH.

Abdominal examination

Examination of the abdomen is usually unremarkable; the liver, spleen and kidneys are often palpable but are rarely significantly enlarged. Hepatosplenomegaly suggests heart failure or sepsis and should be dealt with accordingly, and an easily felt liver in a baby with severe respiratory failure suggests a right tension pneumothorax (p. 484).

Most babies with severe RDS have an ileus (Dunn 1963), and do not pass meconium. Improvement in their general condition is often heralded by the appearance of bowel sounds and the passage of meconium, although gastric emptying may still be delayed. Jaundice is not uncommon; phototherapy and exchange transfusion are indicated in preterm infants at much lower bilirubin levels than in the full-term neonate (Ch. 29.1).

Differential diagnosis (Table 27.7)

The differential diagnosis in the first 6 hours can usually be made on the basis of the history (including the gestation), the clinical examination, the blood gases and the CXR. It is impossible, however, to exclude infection as the cause of the baby's symptoms. Furthermore, infection with group B streptococcus (GBS; *Streptococcus agalactiae*) can coexist with RDS. As a consequence, it is important to treat all infants presenting with respiratory distress with antibiotics until the results of cultures are available. PPHN (p. 495) can be differentiated by the absence of significant parenchymal lung disease and the relevant echocardiographic findings. Infants with RDS, however, may also have marked pulmonary hypertension (Walther et al. 1992). Such infants will have an oxygen requirement that is out of proportion to their CXR appearance and a poor response to surfactant therapy. Respiratory distress presenting after 4–6 hours of age in an infant who has been adequately observed is usually due to pneumonia or heart failure secondary to heart disease. Other conditions, such as aspiration and inhalation of the feed, some malformations and, occasionally, a small pneumothorax can present after 6 hours of age, but these are less common.

Investigations

Haematological

There are no unique haematological findings in RDS. The haemoglobin will vary with the local practice regarding cord clamping (Yao and Lind 1974). Anaemia may develop later due to GMH/IVH (Ch. 40.5) or iatrogenic losses (Ch. 30). Results of measurements of the coagulation system are often prolonged owing to prematurity in infants with RDS, although disseminated intravascular coagulation (DIC) is rare. The presence of a coagulopathy can be due to complications such as birth asphyxia, septicaemia or a GMH/IVH. Infants who have suffered intrauterine growth retardation are also at increased risk of coagulation abnormalities (Hannam et al. 2003). The white blood count is normal for the baby's birthweight and gestation (Manroe et al. 1979). Thrombocytopenia is not a feature of RDS unless there is DIC (Ch. 30).

Biochemical

The plasma electrolyte pattern is usually normal, although marked early hyponatraemia can be seen if the mother has been fluid-overloaded during labour (Tarnow-Mordi et al. 1981). The plasma calcium is frequently low (1.5–1.7 mmol/l) in the first 48–72 hours in ill LBW babies. Although infants of very-low-birthweight (VLBW) are prone to hypoglycaemia, when sick they are also susceptible to hyperglycaemia (Ch. 34.1). Infection should be considered in a

baby with hyperglycaemia. Babies with RDS may have impaired renal function, with a reduced glomerular filtration rate and renal plasma flow and a correspondingly raised urea and creatinine (Guignard et al. 1976); they are also poor at excreting hydrogen ions (Allen and Usher 1971). Fluid restriction has been advocated to improve lung function, but no such effect was seen in a randomised trial (Kavvadia et al. 1998).

Serum albumin levels are often below 25–30 g/l in preterm infants (Carlidge and Rutter 1986) and are lower in the cord blood of babies who develop RDS than in controls (Bland 1972). The albumin may remain below 25 g/l for days or even weeks in critically ill babies; this is the result of albumin leaking into the subcutaneous tissues, poor protein intake and impaired albumin synthesis. Administration of albumin, however, does not improve lung function (Greenough 1998) and may increase the risk of BPD development (Dimitriou et al. 2002c); hence it should be avoided.

Blood gas measurements

Hypoxaemia occurs and can be used to assess the severity of the lung disease. A mixed metabolic and respiratory acidaemia is found in most cases of RDS, with the P_{aCO_2} being raised in all but the mildest cases; indeed, the absence of hypercapnia or the presence of a low P_{aCO_2} should suggest a diagnosis other than RDS in a dyspnoeic neonate (p. 478).

Hormone levels

Cortisol levels of ill 26-week babies are lower than those of healthy preterm babies; they remain low for several days after birth and are further depressed by prenatal therapy with dexamethasone (Kari et al. 1996). Levels of thyroid-stimulating hormone, thyroxine and triiodothyronine, although initially normal in cord blood (Klein et al. 1981), drop below normal during the first week (Franklin et al. 1986).

Echocardiography

Echocardiographic studies in neonates with RDS confirm the presence of a PDA in most cases (Ch. 28), but are otherwise normal in the absence of PPHN or severe depression of myocardial function. Doppler echocardiography is used to investigate the degree of pulmonary hypertension (p. 495).

Measurement of surfactant status

This has limited applicability, as apparently typical RDS can develop in the presence of L:S ratios greater than 2.0, even when PG is present (Wigton et al. 1993), and surfactant-deficient RDS and congenital pneumonia due, in particular, to GBS can coexist. In addition, although assessment of surfactant proteins can be used to determine pulmonary maturity, the tests are expensive and time-consuming. There may, however, be a role for rapid early assessments of neonatal surfactant levels (Chida et al. 1993; Bhuta et al. 1997) if supplies of surfactant are limited.

Chest X-ray

The CXR appearance contributes to the establishment of the diagnosis. In addition, thymic (Fig. 27.14), cardiac and skeletal abnormalities can be identified and the positions of the ETT and indwelling cannulae checked. Classically, in RDS the CXR shows diffuse, fine granular opacification in both lung fields with an air bronchogram where the air-filled bronchi stand out against the atelectatic lungs. In reality, the appearance can be very variable,

Table 27.7 Differential diagnosis of dyspnoea in the neonate

CONDITION	GESTATIONAL AGE	HISTORY	EXAMINATION*	GASES†	PRESENTATION*‡	CHEST RADIOGRAPH	COMMENTS
Respiratory distress syndrome (RDS)	Premature				<6 h +++ N	Diagnostic, but see p. 480	Working diagnosis in all preterm neonates unless chest radiograph suggests alternative. Always consider infection (Ch. 39.2)
Transient tachypnoea	FT > premature [§]	Often caesarean delivery	Mild hypoxaemia needing 40% O ₂		+++ R	Diagnostic, but see p. 485	Commonest cause of breathlessness in term babies. By definition, a mild disease (pp. 485–486)
Meconium aspiration	FTI	Meconium-stained liquor at resuscitation. Postmaturity	Meconium-stained baby. Meconium in larynx		+++ N	Streaky	Diagnosis obvious on history. Infection may coexist
Pneumothorax or pneumomediastinum	FT > premature	May be excessive resuscitation at birth			++ R [¶]	Diagnostic	
Massive pulmonary haemorrhage	Premature > FT	Asphyxia or other cause of heart failure, bleeding tendency. Use of artificial surfactant	Crepitations; usually marked pallor. Blood up larynx or in endotracheal tube. PDA after presentation		+ +++	Unhelpful; usually a white-out	Diagnosis based on clinical findings
After severe asphyxia	FT**	Severe asphyxia Low Apgar	Other features of asphyxia (Ch. 40.4)	Marked metabolic acidaemia	++ N	Unhelpful	Tachypnoea driven by acidaemia
Infection (pneumonia)	Any	May be helpful	Rarely differentiates this from other causes of dyspnoea	Often severe acidaemia and easy to reduce CO ₂ without increasing PaO ₂	++ +++	Unhelpful in most cases, though may show patchy changes	Impossible to exclude in any baby (Ch. 39.2). This is the working diagnosis in the absence of specific chest radiograph findings in neonates >6 hours old with respiratory disease. WBC. CRP may be helpful
Congenital malformations	FT > premature	Usually normal delivery. May have been detected on antenatal ultrasound	Rarely helpful	May be profound hypoxaemia with raised CO ₂	+++ +	Virtually always diagnostic	Diaphragmatic hernia, cysts, effusions, agenesis all present this way. TOF should not present this way (Ch. 29.4)

Congenital heart disease	FT > premature	Murmurs, heart size, signs of heart failure	CO ₂ normal or reduced. In cyanotic CHD PaO ₂ rarely >6–7 kPa even in oxygen with IPPV	R	+++	May be helpful or diagnostic	The alternative common diagnosis in infants presenting after 6 hours and particularly after 24 hours of age. ECG and echocardiogram usually diagnostic
Pulmonary hypoplasia	Any	Prolonged rupture of membranes	No kidneys palpable, amnion nodosum. Dwarf (p. 581)	+++	N	Diagnostic; very small lungs	Virtually always rapidly fatal
Persistent pulmonary hypertension	FT > premature	May have had mild asphyxia	May hear soft murmur of TI	+++	+	Usually normal or nearly so	Can be difficult to exclude cyanotic CHS unless echocardiogram available
Inhalation of feed	Any	Obvious		R	+++	Unhelpful	Should not happen in well-run units. Normal term babies rarely inhale, so always seek alternative diagnosis, especially infection
Inborn errors of metabolism	FT > premature	May be positive family history or history of unexplained neonatal death in the past	No evidence of lung disease. Tachypnoea driven by acidaemia	R	+++	Often normal	Diagnosis based on blood changes plus ketonaemia in many cases (Ch. 34.3)
Primary neurological or muscle disease	FT > premature	May be positive family history or history of unexplained neonatal death or infant death. Polyhydramnios may occur	Marked hypotonia. Areflexia, odd face, deformities. No evidence of lung disease	++	++	Often normal	Usually easy to identify as a group
Upper airway obstruction	FT > premature	May be typical in choanal atresia (p. 604)	Stridor present. Problems resolve on intubation. Laryngoscopy may be diagnostic	++	++	Often normal	

*Mentioning features other than cardinal features of respiratory disease (pp. 476–477).

[†]Most conditions cause hypoxaemia and hypercarbia; only if the blood gas patterns differ from this is it noted here.

[‡]Frequency of presentation graded + to +++; N, never, R, rarely.

[§]Full-term (FT) greater than premature. This means that the condition can occur at any gestation, but since full-term babies are more common than preterm ones, there are more cases in full-term neonates.

If preterm, consider *Listeria*.

[†]Usually as a complication of pre-existing severe lung disease, especially hyaline membrane disease.

^{**}Severely asphyxiated premature babies will get RDS.

PDA, patent ductus arteriosus; WBC, white blood cells; CRP, C-reactive protein; TOF, tracheo-oesophageal fistula; CHD, coronary heart disease; IPPV, intermittent positive-pressure ventilation; ECG, electrocardiogram; TI, inspiratory time; CHS, central hypoventilation syndrome.

Fig. 27.14 Severe respiratory distress syndrome. The lungs are totally opaque and cannot be separated from the heart border because of widespread atelectasis. An air bronchogram can be seen in the right lung.

from a slight granularity to lungs that are so opaque that it is impossible to distinguish between the lung field and the cardiac silhouette. A 'whiteout' on an X-ray taken at 1 hour of age, however, may be due to retained fetal lung fluid. By 4 hours of age, as a result of clearance of the fluid, the CXR appearance may show marked improvement. The CXR appearance also depends on the phase of the respiratory cycle, the appearance being much worse on an expiratory rather than an inspiratory one. Positive-pressure support with both CPAP and IPPV can improve the CXR appearance in a baby who had marked X-ray changes while breathing spontaneously; surfactant treatment has the same effect (Edwards et al. 1985).

Treatment

Initial care

Transportation from the labour ward to the neonatal intensive care unit (NICU)

It is essential to ensure that there is no deterioration in a baby's lung disease during transfer. All VLBW neonates who require intubation for resuscitation should be ventilated in the transport incubator. Ventilator settings during transport are based on the oxygen saturation and the clinical assessment of the baby, in particular whether there is adequate chest wall expansion. Practice differs regarding whether babies who have been intubated to be given surfactant should be extubated on to nCPAP or remain intubated for transfer and assessment can take place on the NICU. Others do not intubate infants routinely in the labour ward, but transfer babies on nCPAP.

Initial management in the NICU

As soon as the baby arrives in the NICU, he or she must be put into an incubator prewarmed to 35–36°C or placed under a radiant heater. In the next 30–60 minutes, the following procedures should be carried out in all neonates with RDS:

- Weigh the infant.
- Examine carefully.
- Measure the head circumference to facilitate diagnosis of the rare infant with a subgaleal haemorrhage and subsequently rapidly enlarging head circumference (Ch. 40.3).
- Connect to electrocardiogram (ECG) and respiration monitors (Ch. 19).
- Measure the baby's temperature.
- Measure P_{aO_2} , P_{aCO_2} and pH. Consider inserting an indwelling arterial line in babies requiring high oxygen concentrations.
- Measure the BP using a continuously recording device once an arterial cannula is in situ, and Dinamap if no cannula is in place.
- Treat abnormalities of blood gases (p. 521).
- Draw blood for haemoglobin and white cell count. Cross-match all ill neonates, as most eventually need transfusion.
- Take a set of cultures, including a blood culture; a lumbar puncture is not required for all infants (Ch. 39.2). A blood sample for culture can be taken from the UAC during the sterile insertion routine.
- Send blood for electrolyte measurement: this establishes a baseline and identifies early abnormalities due to problems with maternal fluid balance.
- Measure coagulation levels in ill and bruised babies and those less than 30 weeks' gestation.
- Insert a peripheral cannula for the administration of antibiotics.
- In critically ill infants or those with extremely low birthweight (ELBW), insert umbilical arterial and venous catheters.
- Obtain a CXR, preferably after inserting the UAC.
- Give surfactant, if it has not been given prophylactically in the labour ward (Ch. 13.1).
- Update the parents.

General management of the baby with RDS

Minimal handling

If hypoxic babies are disturbed and handled, their respiration may become very irregular or stop altogether, their right-to-left shunt increases and their P_{aO_2} falls rapidly. Major disturbances, such as sucking out an ETT, performing a lumbar puncture or taking a CXR, can cause catastrophic falls in P_{aO_2} . The 'minimal handling' maxim dominates the whole approach to managing all sick babies with RDS.

Physiotherapy

In the first 24–48 hours, secretions are not a problem unless infection develops. As a consequence, chest physiotherapy and routine suctioning of the ETT are contraindicated.

Temperature control

The baby's thermal environment should be controlled and, if babies are exposed during any procedure, they should be under a radiant heat source, with as much of their surface as possible covered in order to minimise heat losses.

Blood gas management

Abnormalities of P_{aO_2} , P_{aCO_2} and acid-base metabolism are characteristic of RDS, and keeping the blood gases within a reasonably normal range is the single most important component of the treatment. The detailed management of oxygen administration, CPAP and IPPV are covered on pages 517–523.

Pao₂

The *Pao₂* drawn from a UAC distal to the ductus should be maintained in the range 7–10 kPa (50–75 mmHg). Nowadays many units use pulse oximetry to monitor preterm infants, but the success of maintaining pulse oximeter saturation levels varies between and within centres (Hagadorn et al. 2005) and this is not a method of monitoring for very prematurely born infants at high risk of ROP.

Paco₂

The *Paco₂* in a normal newborn baby is in the range 4.6–5.4 kPa (35–40 mmHg). Cerebral blood flow increases about 30% with each 1 kPa increase in *Paco₂*. A degree of permissive hypercarbia has been associated with a reduced incidence of BPD (Garland et al. 1995) but comparison, however, of *Paco₂* target levels of 55–65 mmHg (minimal ventilation) and 35–45 mmHg revealed the latter was associated with a trend towards a higher mortality and neurodevelopmental impairment at 22 months of age (Thome et al. 2006). Hypercarbia in the early days of life remains a risk factor for IVH and we advise caution in the use of this approach during the acute phase of RDS (Thome and Carlow 2002; Kaiser et al. 2006). Higher *Paco₂* levels in more mature neonates with RDS and in <1.50-kg infants more than a week old who are being weaned off IPPV are acceptable, providing the baby is clinically stable with satisfactory pH and base excess levels. Hypocapnia (*Paco₂* <3.3 kPa) should be avoided because of its role in the genesis of PVL (Ch. 40.5). A rapidly rising *Paco₂* is a sign of impending respiratory failure, usually associated with a fall in pH, and therefore indicates that the baby should be intubated and ventilated irrespective of postnatal age. More gradual changes with an acceptable pH (>7.25) can be managed conservatively, particularly when the baby is not in the acute phase of illness.

pH

Metabolic alkalaemia is rare and almost always iatrogenic as a result of excessive amounts of intravenous bicarbonate having been given. It requires no therapy. Respiratory alkalaemia is usually due to excessive ventilator pressures.

Acidaemia is common in neonates with RDS. It is always essential to establish whether the acidaemia is respiratory with a raised *Paco₂*, or metabolic with a normal *Paco₂* and a negative base excess, or a combination of a metabolic and respiratory acidosis, which is more usual. The commonest cause of a metabolic acidaemia in a baby with RDS is a raised lactate from anaerobic metabolism. This in turn can be secondary to hypoxaemia, hypotension, anaemia or infection. When a metabolic acidaemia does develop, it is essential to identify the cause, so direct treatment can be instituted – for example, oxygen for hypoxia, antibiotics for infection, transfusion for anaemia or IPPV for exhaustion.

Acidaemia inhibits surfactant synthesis (p. 462) and increases pulmonary vascular resistance (Rudolph and Yuan 1966). Once the pH falls below 7.15, other physiological functions such as myocardial contractility (Beierholm et al. 1975) and diaphragmatic activity (Howell et al. 1985) begin to deteriorate. The sick neonate has difficulty in excreting an acid load (Allen and Usher 1971). Ill VLBW neonates should have their pH kept >7.25 at all times. If the pH is <7.25 with a base deficit <10 mmol/l, intravenous alkali therapy is appropriate, if other therapies are not immediately successful. Inappropriately large or fast infusions of base to correct metabolic acidaemia, however, may cause hypernatraemia or cerebral haemorrhage. Two alkalis have been used in neonatal therapy, sodium bicarbonate and trishydroxymethylaminomethane (THAM); both are effective. The theoretical risk that, following

infusion of bicarbonate, the cerebrospinal fluid might become even more acidotic does not seem to apply to the neonate. THAM administration does not give a sodium load or increase the *Paco₂* and is preferable to bicarbonate if the neonate has a high *Paco₂* but apnoea may result and thus THAM should only be given to ventilated neonates. The dose of base to be given is calculated as:

$$\text{Dose (mmol)} = \text{base deficit (mmol/l)} \times \text{body weight (kg)} \times 0.4$$

The rate of infusion should never exceed 0.5 mmol/min. Seven per cent THAM solution contains approximately 0.5 mmol/ml of base.

Blood pressure

All neonates suffering from RDS must have their BP monitored regularly (Ch. 19). It is important to determine whether a baby is hypotensive because he or she is anaemic. In general, the first transfusion should be 15 ml/kg given by infusion over 10–15 minutes if the hypotension is severe in the first hours after birth; thereafter, transfusions of blood or albumin are better given more slowly, at a rate guided by the condition of the neonate, clinical response and the BP rise during the transfusion. Transfusions should also be given to babies who are not hypotensive but have features suggesting hypovolaemia, such as poor capillary filling, peripheral vasoconstriction and a falling pH, coupled with the record of large volumes of blood having been removed for analysis. There is, however, no place for routine plasma expanders soon after delivery (NNTI Trial Group 1996). If the neonate's haemoglobin is not low, saline should be given rather than albumin, because the response to albumin is small and rarely sustained (Emery et al. 1992) and it has adverse effects. If the hypotensive neonate is severely hypoxic or acidaemic, cardiac function may be impaired and the baby will tolerate volume expansion badly, in which case dopamine is the preferred treatment (Gill and Weindling 1993). Dopamine should also be used in those in whom volume expansion has failed to increase BP; trials have shown it to be more effective than dobutamine (Emery and Greenough 1993; Klarr et al. 1994). The actions of dopamine are complex (Seri 1995). At 0.5–2.0 µg/kg/min, dopaminergic actions dilate renal, mesenteric and coronary arteries; from 2 to 10 µg/kg/min, myocardial contractility is increased directly by both α- and β-receptor-mediated actions and also by the release of noradrenaline (norepinephrine) from cardiac adrenergic nerves. At doses above 10–15 µg/kg/min, dopamine begins to show α-adrenergic activity and is a vasoconstrictor of all vascular beds. Initially, therefore, 2–4 µg/kg/min should be given (Seri et al. 1993), increasing the dosage until the BP is acceptable.

If plasma volume expansion plus dopamine does not reverse hypotension, other agents can be tried:

- Dobutamine. This is an isoprenaline analogue with a primarily β-adrenergic inotropic effect on the myocardium, with little peripheral vascular effect, and no specific effect on the renal vascular bed.
- Isoprenaline. This beta-mimetic drug has a chronotropic and inotropic effect and is therefore of greatest benefit if hypotension is accompanied by bradycardia. It is not useful in shock because of its peripheral vasodilator effects.
- Adrenaline (epinephrine). This increases BP by peripheral vasoconstriction plus increased myocardial contractility. Its vasoconstrictor effects on the renal vasculature are clearly undesirable.
- Dopexamine hydrochloride. This is a synthetic catecholamine with predominant β₂-adrenergic and dopaminergic activity. In low doses (2–4 µg/kg/min) it can improve BP and urine

output (Kawczynski and Piotrowski 1996), but at higher doses it reduces systemic vascular resistance.

- Hydrocortisone 1–2 mg may be successful (Helbock et al. 1993).

Maintenance of haemoglobin

There are many reasons for a preterm neonate being anaemic (Ch. 30). There may have been an intrapartum haemorrhage, defective placental transfusion or a twin-to-twin or fetomaternal haemorrhage. Blood loss after birth is iatrogenic, but a sudden drop in the haematocrit/haemoglobin level in a baby with RDS suggests the development of a GMH/IVH (Ch. 40.5). Ill neonates, in particular those who are premature, tolerate haemoglobin levels <13 g/dl (packed cell volume (PCV) <40) poorly (Strauss 1995). This is presumably because of the increase in cardiac output required to meet the oxygen demands of the tissues when there is reduced blood oxygen-carrying capacity. One policy, therefore, is to transfuse all ill neonates when their haemoglobin has fallen below 13 g/dl (PCV <40) (James et al. 1997). Blood for transfusion should be from a cytomegalovirus-negative donor and be partially packed to a haemoglobin level appropriate for a premature baby (PCV 40–45%), but it does not need to be fresh blood, as the adverse metabolic features of 2–3-week-old donor blood are of no clinical significance when given as a 15 ml/kg transfusion over 30–120 minutes. The blood should be irradiated to avoid the risk of graft-versus-host disease (Ch. 30). If the baby has a clinically important patent ductus, he or she should receive furosemide 1.0 mg/kg during the transfusion; otherwise, there is no need to give diuretic cover. Transfusions may be needed several times a week during the acute phase of the illness and should be continued for as long as the baby is ventilated or has BPD requiring more than 30–40% oxygen. With modern transfusion practice, donor exposure can be reduced to a minimum (Ch. 30).

Coagulation abnormalities

Routine administration of fresh frozen plasma soon after birth is of no benefit (NNNI Trial Group 1996), but it is important to check for coagulation disorders, as these may be of sufficient magnitude to require treatment, particularly in a baby who is small for gestational age (Hannam et al. 2003).

If an overt coagulation disturbance occurs, such as DIC or thrombocytopenia, this should be treated by appropriate factor replacement (Ch. 30), but it is also essential to control and reverse the underlying problem, such as hypoxaemia or sepsis, which caused the coagulopathy in the first place.

Fluid and electrolyte balance (see Ch. 18)

Renal function is often impaired in RDS. Urine production may be no more than 1.0–1.5 ml/kg/h, close to the definition of oliguric renal failure (1 ml/kg/h) (Ch. 35.1); however, peripheral oedema is usually due to leaky capillaries. Sodium and potassium do not usually need to be added to the fluid intake for the first 36–48 hours, though the frequent presence of hypocalcaemia in such babies (Chs. 34.3 and 34.4) means that calcium should usually be given (Ch. 17).

Antidiuretic hormone (ADH) levels are raised in babies with RDS, particularly when they are very ill (Rees et al. 1980) or after they develop a pneumothorax (Paxson et al. 1977; Wiriyathan et al. 1986). Babies who develop BPD have particularly raised ADH levels in the first few days after birth (Kavvadia et al. 2000b). Plasma levels of atrial natriuretic peptide are also high in the first few days in babies with RDS (Shaffer et al. 1986). There is a complex interrelationship between atrial natriuretic peptide levels, ductal

shunting with atrial distension in RDS and the postnatal natriuresis that appears to be an integral part of the recovery phase of RDS (Ch. 18) (Kääpä et al. 1995). The increased capillary permeability in RDS results in fluid loss into all tissues, including the lungs.

Analysis of randomised trials demonstrates that restricted water intake significantly increases postnatal water loss and significantly reduces the risk of PDA and NEC (Bell and Acarregui 2008). We therefore recommend that infants with RDS should start on 40–60 ml/kg/24 h of a 10% dextrose solution or a suitable 'standard bag' of total parenteral nutrition (TPN) to avoid catabolism. For further advice on fluid balance, see Chapter 18.

Characteristically, diuresis occurs around the time the baby's lung function improves (Kavvadia et al. 1998). Once this happens, previous constraints on the fluid balance to 40–60 ml/kg/24 h need to be relaxed to prevent dehydration, haemoconcentration and worsening jaundice.

Albumin

Hypoalbuminaemia, with a low colloid osmotic pressure predisposing to tissue oedema, is common in RDS. Infusions of albumin, however, do not improve respiratory function (Gonzales et al. 1986); indeed, they may impair it (Kavvadia et al. 1998) and increase the risk of BPD (Dimitriou et al. 2002c).

Nutrition in RDS

Since the protein and caloric reserves of the VLBW neonate are small, it is essential that some form of nutrition, including protein, is given as soon after birth as possible. Neonates with severe respiratory illness may have an ileus and delayed gastric emptying; bowel sounds are absent and meconium is not passed. Enteral feeding initially may not be feasible in some ventilated babies <1.5 kg or some larger sick neonates. Parenteral nutrition, initially amino acids and glucose, should be given (see Ch. 17). There have been anxieties regarding the use of intralipid in neonates with severe lung disease, in whom it may cause a fall in P_{aO_2} by increasing pulmonary vascular resistance (Prasertsom et al. 1996).

Milk in the stomach may compromise ventilation, increase the work of breathing (Heldt 1988), lower the P_{aO_2} and even cause apnoea. In spontaneously breathing babies, respiratory problems may be aggravated by the presence of a nasogastric tube obliterating one-half of the upper airway (Greenspan et al. 1990). However, gastro-oesophageal reflux (GOR), NEC and the physiological changes mentioned do not appear to be a major problem in VLBW neonates (Newell et al. 1989b), even in those who are ventilated and with an indwelling UAC, provided that milk (ideally breast milk; see Ch. 16) is only given to babies with clear evidence of bowel activity. Furthermore, there are powerful reasons for attempting to introduce enteral feeds as soon as possible; the prolonged absence of enteral feeding compromises gut growth, the development of enzymes and normal peristaltic activity, and limits early weight gain. The sooner enteral feeding is attempted in VLBW neonates, the sooner full enteral feeding is established (Lucas et al. 1986; Troche et al. 1995). Thus, once bowel sounds are present in a ventilated neonate who is appropriately grown and has passed meconium, irrespective of whether or not there is an indwelling UAC (Troche et al. 1995), enteral feeding should be started, using if possible the mother's milk (Ch. 16).

Drug therapy in RDS

Antibiotics

It can be difficult to differentiate severe early-onset septicaemia from severe RDS and both conditions may coexist. Without

antibiotic treatment, early-onset septicaemia can be fatal within hours (Ch. 39.2). For this reason, all dyspnoeic newborn babies, irrespective of their gestation or CXR appearance, should have appropriate bacterial cultures taken and be treated with antibiotics from the earliest signs of respiratory illness. Penicillin and gentamicin are appropriate therapy as they act synergistically against GBS and are also effective against many of the other organisms that cause early-onset septicaemia and pneumonia. In babies with RDS who are stable or who are improving, antibiotics should be stopped when negative culture results are notified at 48–72 hours.

Diuretics

There have been several trials of diuretics in preterm infants with RDS; no long-term benefits were reported (Brion and Soll 2008). Diuretics should be reserved for infants who are oliguric and have obvious signs of fluid retention and deteriorating lung function. The response to a dose of 1 mg/kg furosemide should be evaluated. If a diuresis does not result, a combination of furosemide and dopamine may be effective.

Vitamins

Vitamin K should be given to all neonates (Ch. 30).

Pulmonary vasodilators

Pulmonary hypertension should be suspected in infants whose hypoxia is more severe than would be anticipated from their CXR appearance. Administration of pulmonary vasodilators can result in an improvement in oxygenation, but all have side-effects (p. 498). Randomised trials have not demonstrated any long-term benefits of administering inhaled nitric oxide (iNO) to prematurely born infants (p. 499) (Finer and Barrington 2009).

Analgesia/sedation

Appropriate analgesia/sedation should be given to ventilated infants (see below and Ch. 25) and analgesia administered prior to a painful procedure being undertaken. Sedation is contraindicated in infants with RDS who are breathing spontaneously. Infants who are electively intubated should receive premedication; effective regimes are a combination of atropine, an analgesic (such as fentanyl) and a muscle relaxant (such as mivacurium or succinylcholine) (Dempsey et al. 2006; Lemyre et al. 2009).

Methylxanthines

Methylxanthines are of proven benefit in apnoea of prematurity (p. 571) and in weaning babies less than 30 days old from IPPV (p. 528). Caffeine with its wider therapeutic margin is the agent of choice. In a large randomised trial, caffeine administration was associated with a lower incidence of BPD and better neurodevelopmental outcome (Schmidt et al. 2006, 2007). In spontaneously breathing babies with RDS, apnoeic attacks are usually a sign of impending ventilatory exhaustion (Davis and Bureau 1987) and are then an indication for IPPV.

Indometacin

The use of indometacin in preventing or treating a patent ductus is discussed in detail in Chapter 28.

Surfactant therapy

Surfactant given as 'rescue' therapy improves the outcome in babies with established RDS, resulting in a reduction in pneumothorax, mortality and the combined outcome of mortality and BPD (Seger and Soll 2009; Soll 2009b).

Method of administration

The surfactant preparation is delivered over a period of a few seconds down the ETT. The surfactant usually disseminates homogeneously (Davis and Whitin 1992), particularly if large rather than small doses are used (van der Bleek et al. 1993). As might be expected, deposition is influenced by gravity, with dependent parts of the lung receiving more of the dose (Broadbent et al. 1995). There seems, however, to be no benefit from manoeuvres aimed at trying to improve the distribution to different lobes (Yukitake et al. 1995).

To avoid mechanical ventilation, surfactant has been given via a thin ETT to spontaneously breathing infants receiving CPAP (Kribs et al. 2007). In a subsequent observational study, the same centre reported that technique of administration was associated with increases in the use of CPAP and survival without BPD (Kribs et al. 2008). Appropriately designed trials are required to determine whether such a technique offers long-term advantages.

Mechanism of action

Exogenous surfactant works in two ways: firstly, by coating the alveolar surface and elevating lung volume, thus improving oxygenation and pulmonary perfusion. A fall in PAP and a rise in pulmonary blood flow and left-to-right ductal shunting have been reported in most studies (Seppänen et al. 1994; Hamdan and Shaw 1995), but not all (Bloom et al. 1995). Secondly, exogenous surfactant administration is incorporated into the type II cells and can provide substrate for, or even stimulate, surfactant production (Oetomo et al. 1990; Pinkerton et al. 1994).

Size and number of doses

Although beneficial effects, both clinically and physiologically, are seen after a single dose of surfactant, usually in the range of 100 mg/kg (Corbet et al. 1991; de Winter et al. 1994), most studies show that better results are obtained with more than one dose. The Osiris trial (Osiris Collaborative Group 1992), however, showed no benefit of three or four doses of Exosurf compared with two doses. Meta-analysis has demonstrated that multiple doses give a better outcome than a single dose, with a significant reduction in the pneumothorax rate (Soll 2000b). Meta-analysis of trials of animal-derived surfactants (Soll and Ozek 2009) demonstrated that multiple doses improved oxygenation and decreased the risk of pneumothorax.

Variation in response

Not all babies respond to surfactant. Factors that lead to an unsatisfactory response include the presence of a PDA, cardiogenic shock or PPHN and airleaks, which in some cases will lead to protein leaking on to the alveolar surface, impairing surfactant function (Frantz and Close 1985; Kinsella and Abman 1995). Infants who have been exposed to chorioamnionitis may have a poorer response to surfactant (Been et al. 2010). Failure to respond to surfactant marks out a group of babies with a worse prognosis (Skelton and Jeffrey 1996). Very premature infants may suffer a postsurfactant slump: in an uncontrolled study 70% of affected infants responded to a repeat course after day 6 of life (Katz and Klein 2006).

Different types of surfactant

Natural surfactants, as they more closely mimic the 'physiological' mixture of lipids and proteins (SP-B and SP-C), have a more rapid effect on oxygenation than do synthetic surfactants. Meta-analysis of randomised trials comparing natural and synthetic surfactants demonstrated that the natural surfactant was associated with significant reductions in mortality and pneumothorax and a marginal

increase in IVH, but not in grade 3 or 4 IVH (Soll and Blanco 2009). The synthetic surfactant (Lucinactant) containing a polypeptide KL4 composed of lysine and leucine (Cochrane et al. 1996) appears to be as resistant as natural surfactants to the inhibitory effects of proteins on the alveolar surface (Manalo et al. 1996).

Side-effects during the administration of the surfactant

There may be transient hypoxaemia and bradycardia. There were initial anxieties that, following surfactant instillation, there was either a fall (Cowan et al. 1991) or a rise in cerebral blood flow velocity (van Bel et al. 1992) and even an increase in GMH/IVH (Collaborative European Multicentre Study Group 1991). Systemic hypotension and a transient flattening of the electroencephalogram (EEG) were also reported (Cowan et al. 1991; Hellstrom-Westas et al. 1992). More detailed studies have shown little more than a transient perturbation in cerebral haemodynamics, without evidence of cerebral ischaemia, if care is taken with the surfactant instillation (Edwards et al. 1992; Bell et al. 1994; Lundstrom and Greisen 1996) and the pooled data show either no effect or even a slight reduction in the incidence of GMH/IVH following surfactant administration.

Swamping alveolar macrophages with instilled surfactant could, in theory, increase the baby's susceptibility to infection (Schrod et al. 1996), but no clinical evidence has been found of such an association. Anxiety has been expressed that immune responses to exogenous surfactant proteins instilled into the lung would cause short- or long-term problems, but none has been reported. Surprisingly, antibodies to surfactant proteins have been found in both surfactant- and placebo-treated infants (Chida et al. 1991).

Pulmonary haemorrhage (MPH), particularly in ELBW neonates, has been noted following surfactant administration, this was increased (doubled) with the use of a synthetic surfactant (Exosurf) (Stevenson et al. 1992; Raju and Langenberg 1993).

Follow-up studies have not demonstrated any additional neurological deficits in surfactant-treated survivors (Morley and Morley 1990; Long et al. 1995) nor any increase in severe ROP (Termote et al. 1994). Surfactant-treated infants may have improved long-term lung function compared with untreated controls (Abbasi et al. 1993; Yuksel et al. 1993b).

Monitoring

The general principles of monitoring the ill preterm neonate are laid out in Chapter 19.

Complications

Many of the complications are dealt with in detail elsewhere and will be only briefly summarised below.

Airleaks, pneumothorax, pulmonary interstitial emphysema (p. 490)

In the past, some form of airleak was reported in about 5% of babies with RDS who were breathing spontaneously; the incidence doubled with CPAP and rose to as high as 35–40% in babies treated with IPPV plus positive end-expiratory pressure (PEEP) and inspiratory times exceeding 1 second. Nowadays, with the use of synchronised IPPV (p. 517) and surfactant (p. 459), the overall incidence of airleaks is less than 10% in ventilated infants.

Patent ductus arteriosus

The incidence of symptomatic PDA is increased by fluid overload (Bell et al. 1980). A clinically significant ductus in a ventilated

preterm baby presents as signs of heart failure and a loud precordial murmur filling systole, frequently extending into diastole. The oxygen and ventilatory requirements increase and affected babies may develop massive pulmonary haemorrhage (p. 509). Management is outlined on pages 511–512.

Germinal matrix/intraventricular haemorrhage (see Ch. 41, part 5)

The development of a large GMH/IVH is usually associated with clinical deterioration characterised by anaemia, increased ventilatory requirements and abnormal neurological signs, which can be subtle (Ch. 40.1). In many cases, smaller GMH/IVHs are asymptomatic and detected only on routine ultrasound. Many aspects of the management of respiratory failure in the neonate are directed towards preventing GMH/IVHs, for example avoiding procedures which might provoke surges in cerebral blood flow, including the avoidance of hypercarbia and wide swings in P_{aCO_2} and correcting coagulation disturbances.

Bronchopulmonary dysplasia

This is a most important complication of RDS in terms of morbidity, duration of therapy and associated costs. It is described in detail in Chapter 27, part 3.

Renal failure

One of the purposes of attempting early correction and maintenance of BP, using dopamine to preserve renal perfusion and paying meticulous attention to the fluid balance in babies with RDS, is to sustain renal function. In some cases this is not successful, and in others an acute episode of collapse, such as may occur with bilateral tension pneumothoraces, results in acute tubular necrosis (Ch. 35.1). If renal failure develops, it should be treated as outlined in Chapter 35, part 1. If biochemical control cannot be achieved, then either peritoneal dialysis or haemofiltration may be used. Haemofiltration avoids the major problem with peritoneal dialysis, which is that the intraperitoneal fluid splints the diaphragm and makes oxygenation difficult in ventilated neonates.

Outcome

Survival

Death from RDS in a baby weighing more than 1.5 kg is now exceptionally rare and the overall mortality from the condition has been reduced to between 5% and 10%.

Sequelae

Readmission to a general paediatric ward in the first 2 years after birth is common, but after that age readmissions are infrequent (Greenough et al. 2004). Amongst VLBW infants, infants with birthweight <750 g and gestational age of less than 28 weeks require the greatest number of admissions and longest duration of stay. In the first year, the duration of stay is inversely related to birthweight (Yuksel and Greenough 1994). Readmissions are particularly likely in infants who developed BPD and subsequently suffered a respiratory syncytial virus infection (Greenough et al. 2001). Other causes of readmission include sequelae of surgery for NEC, failure to thrive and repair of an inguinal hernia, which is common in males with a birthweight of less than 1.00 kg.

Respiratory

The most important respiratory sequel of RDS is BPD (Ch. 27.3). Airway problems secondary to prolonged intubation may also occur (p. 610). After discharge, babies who have survived RDS in the neonatal period are more likely to have respiratory illness, particularly in the first year after birth, than are infants born at term or prematurely without respiratory problems. Preterm babies have lung function abnormalities at follow-up: an increased airways resistance and air trapping. These sequelae are more common in neonates who required prolonged ventilation and they are particularly severe in those who developed BPD (Ch. 37.3).

Long-term neurological sequelae

See Chapter 3.

Transient tachypnoea of the newborn

Incidence

This is between 4 and 5.7 (Morrison et al. 1995) per 1000 infants delivered between 37 and 42 weeks of gestation. TTN does occur in prematurely born infants, although coexisting problems such as RDS may mask the presentation; an incidence of 10 per 1000 has been reported in all babies born in 65 hospitals (Dani et al. 1999), which is higher than in term infants.

Aetiology

TTN is due to a delay in fetal lung fluid clearance (Avery et al. 1966a). It is more common in infants who are born by caesarean section without labour (Morrison et al. 1995). In babies who develop TTN, noradrenaline (norepinephrine) levels are lower than in those delivered following labour (Greenough and Lagercrantz 1992). In the absence of labour, anticipatory lung fluid clearance has not occurred (p. 449) (Walters and Olver 1978).

The relative risk for respiratory distress after birth by caesarean section without labour has been reported to be 1.74 if delivery occurs at 37 rather than 38 weeks of gestation (Morrison et al. 1995). Similarly, TTN and RDS were found to be more common in twins delivered by caesarean section if this was performed prior to 38 weeks of gestation (Chasen et al. 1999). Others (Lewis et al. 1996), however, have suggested that respiratory morbidity may only be increased by delivery by caesarean section if this occurs prior to the 36th week of gestation.

Respiratory distress after elective caesarean section in babies born at term may be due to surfactant deficiency per se (Madar et al. 1999), but surfactant deficiency may also be important in the pathogenesis of TTN (James et al. 1984). Other risk factors for TTN include male sex (Dani et al. 1999; Webb and Shaw 2001) and a family history of asthma (Schatz et al. 1991; Demissie et al. 1998; Schatz 1999). The proposed mechanism for the association of TTN and maternal asthma is that infants of asthmatic mothers have a genetic predisposition to β -adrenergic hyporesponsiveness (Schatz et al. 1991). Resorption of fetal lung fluid is a catecholamine-dependent process; it has been reported (Currie et al. 2010) that beta 1 and 2 adrenoreceptor polymorphisms, known to alter catecholamines, are operative in TTN. NO polymorphisms were not detected in the second transmembrane-spanning domain of the epithelial sodium channel (Landmann et al. 2005).

Presentation

The classical presentation is isolated tachypnoea with respiratory rates up to 100–120/min. The infants rarely grunt, which is a sign indicating atelectasis. Retraction, indicating non-compliant lungs, is minimal. The chest may be barrel-shaped as a result of hyperinflation, and the liver and spleen are palpable because of downward displacement of the diaphragm. Peripheral oedema is often present and affected babies lose weight more slowly than controls (Rawlings et al. 1984). On auscultation, there may be added moist sounds, similar to those heard in heart failure. Tachycardia is common, but the BP is usually normal. TTN usually settles within 24 hours, but may persist for several days. Some infants with TTN have been reported to require high concentrations of supplementary oxygen (Halliday et al. 1981), even 100% oxygen for several days (Bucciarelli et al. 1976) or IPPV (Tudehope and Smyth 1979), but whether such patients had TTN is arguable.

Investigations

Affected infants usually have a mild hypoxia; a marked respiratory or metabolic acidosis is unusual, and, if present, makes a review of the diagnosis mandatory. The CXR shows hyperinflation, prominent perihilar vascular markings, oedema of the interlobar septa and fluid present in the fissures (Dani et al. 1999) (Fig. 27.15). The prominent perihilar streaking is due to engorgement of the periaortic lymphatics, which participate in the clearance of lung fluid; fluid may also be present in the costophrenic angles. The CXR usually clears by the next day, although complete resolution may take 3–7 days. Lung ultrasonography shows a difference in lung echogenicity between the upper and lower lung areas in infants with TTN; comet-like tails have been seen in the inferior fields, which were not seen in the healthy controls (Copetti and Cattarossi 2007; Aslan et al. 2008). Infants with TTN have a reduced tidal volume, but a raised minute volume due to the increased respiratory rate. Compliance is reduced; airways resistance and FRC are raised (Sandberg et al. 1987b).

Fig. 27.15 Transient tachypnoea of the newborn. There is fluid in the right horizontal fissure and pulmonary venous congestion.

Differential diagnosis

A rapid respiratory rate may be due to cerebral irritation from sub-arachnoid blood or perinatal hypoxic ischaemia (Ch. 40.3), but these infants are distinguished by their history and the presence of a respiratory alkalaemia. The CXR appearance of TTN may be mimicked by heart failure. If the heart failure is due to asphyxia, there will be a positive history and the heart will usually be enlarged; if it is due to congenital heart disease, a murmur may be present. It is not possible to differentiate TTN from early-onset sepsis (Ch. 39.2) and this needs to be considered when planning the initial treatment.

Prevention

Continuous infusion of terbutaline given to mothers prior to elective caesarean section was associated with improved lung function in their offspring (Eisler et al. 1999), but the mothers who received terbutaline had significantly higher levels of bleeding.

Treatment

Most infants with TTN require no form of respiratory support other than added oxygen and rarely require an inspired oxygen concentration greater than 40% or support for more than 3 days. Intravenous penicillin and gentamicin should be administered until infection has been excluded (Ch. 39.2). Hydration should be maintained with intravenous glucose electrolyte solutions, and nasogastric tube feeds withheld until the respiratory rate settles. Diuretics are of no proven benefit (Wiswell et al. 1985; Lewis and Whitelaw 2002). In a randomised trial, although infants who were given oral furosemide 2 mg/kg followed by 1 mg/kg 12 hours later lost more weight than the placebo group, there were no significant differences between the two groups with regard to the durations of tachypnoea or hospitalisation or the severity of symptoms (Lewis and Whitelaw 2002).

Monitoring

The standard monitoring outlined in Chapter 19 should be applied. A UAC should be inserted if the baby has a persisting requirement for more than 40% oxygen.

Complications

These are rare, though airleaks may occur, particularly if the baby requires CPAP or IPPV.

Prognosis

The condition is self-limiting, although the symptoms may last throughout the perinatal period. There is debate whether babies who have had TTN are more likely to wheeze at follow-up (Shohat et al. 1989; Schatz et al. 1991).

Minimal respiratory disease

Minimal respiratory distress is usually diagnosed if transient respiratory signs persist for less than 4 hours (Hjalmarson 1981).

Aetiology

Some babies are hypothermic, with a temperature of less than 35°C. Surfactant function is temperature-dependent (Gluck et al.

1972) and the babies often improve within an hour or two when their temperature returns to normal. Some babies have a moderately low pH at 7.20–7.25, which may transiently compromise surfactant synthesis (Merritt and Farrell 1976). The tachypnoea may be the result of mild intrapartum asphyxia with or without minor degrees of aspiration of meconium or amniotic squames. In most cases, the condition probably represents the very mild end of the spectrum of delayed clearance of lung liquid, which in the more marked form is diagnosed as TTN.

Clinical features

The baby, near or at term, presents within the first 2–3 hours, commonly after being transferred to the postnatal ward with the mother. The infant usually has an expiratory grunt, which may be quite loud; there is mild sternal or intercostal recession and a respiratory rate of up to 80–100/min. Cyanosis, if present, is relieved by administering 25–30% oxygen. There are no added sounds in the chest and the rest of the clinical examination is normal.

Differential diagnosis

This is always a retrospective diagnosis, made once the baby has recovered and shows no signs of infection or more serious pulmonary disease. The major anxiety when the baby first presents is whether the diagnosis is early-onset sepsis (Ch. 39.2). In some infants with mild pulmonary hypoplasia tachypnoea is the only presenting feature (Aiton et al. 1996); such cases, however, can be distinguished by the persistence of the tachypnoea, small-volume lungs on CXR and abnormal lung function tests.

Investigations

It is advisable to check the infant's blood gas, take a CXR to exclude other diagnoses and undertake a blood count and blood culture. Hypoglycaemia should be excluded, particularly if the baby's mother has diabetes or the baby is small for dates. The blood gas analyses will usually show mild hypoxaemia in air (P_{aO_2} 6–8 kPa, 45–60 mmHg), which rapidly becomes normal in 25–30% oxygen; P_{aCO_2} and the pH will usually be normal or there will be a mild metabolic acidaemia, with a pH of 7.20–7.25 and a base deficit of 10 mmol/l. The haemoglobin and white cell count will be normal. The CXR, particularly if taken within 1–2 hours of birth, often shows some streakiness or a rather non-specific haziness, both of which probably represent delayed clearing of the fetal lung liquid, but this is not an indication for an early CXR, i.e. before 4 hours (p. 480).

Treatment

Antibiotics should be given to all infants with respiratory distress, as infection cannot be excluded until the results of the cultures are available at 48 hours after birth.

Prognosis

The prognosis is excellent. Most babies are asymptomatic by 12 hours of age.

Pulmonary airleaks

Pneumothorax and pulmonary interstitial emphysema (PIE) are the most common forms of airleaks in the newborn;

pneumomediastinum, pneumopericardium and pneumoperitoneum also occur. Rarely, multiple airleaks may be complicated by subcutaneous emphysema and systemic air embolism.

Pathophysiology

Pulmonary airleaks occur when there is uneven alveolar ventilation, air trapping and high transpulmonary pressure swings; the final common pathway is alveolar overdistension and rupture. Uneven ventilation is compounded by a lack of redistribution of pressure through the alveolar connecting channels, the pores of Kohn, which are reduced in number in the immature lung (Macklin 1936). The rupture is thought to occur at the alveolar bases, in apposition to blood vessels. The gas tracks along the sheaths of pulmonary blood vessels to the mediastinum, where it accumulates in the roots of the lungs; air may then rupture into the pleura, mediastinum, pericardium or extrathoracic areas. The existence of PIE supports this hypothesis, as, after alveolar rupture, gas is trapped in the parenchyma by the extensive connective tissue matrix and increased interstitial water in the preterm lung. This prevents decompression into the mediastinum, thereby splinting the lung and compressing the blood vessels. An alternative hypothesis is that interstitial air directly enters the pleural cavity after rupture of a subpleural bleb (Plenat et al. 1978).

Pneumothorax

Incidence

An early study (Steele et al. 1971), which involved X-raying the chest of all newborns, demonstrated that 1% had airleaks, although only 10% of those with airleaks were symptomatic. The incidence was reported to be higher if there was associated lung disease or the neonate was receiving assisted ventilation; 4% of infants with lung disease developed airleaks, compared with 16% in infants receiving CPAP and 34% in those requiring mechanical ventilation (MacFarlane and Heaf 1988). In the last two decades, the incidence of pneumothorax has decreased in response to the use of surfactant therapy (p. 459), pancuronium (p. 488) and fast ventilator rates (p. 519), with most units reporting airleak rates of less than 10% in ventilated babies.

Aetiology

Spontaneous pneumothoraces may occur immediately after birth owing to the high transpulmonary pressure swings generated by the newborn during his or her first breaths (Vyas et al. 1986) or because of active resuscitation. Familial spontaneous pneumothoraces occurring in neonates are very rare (Engdahl and Gershan 1998). Pneumothoraces in one series (Zanardo et al. 2007) were commoner following elective than emergency caesarean section or vaginal births. There was a significant progressive reduction in the incidence of pneumothorax when the elective caesarean sections were performed from 37 weeks onwards (Zanardo et al. 2007). Pneumothorax is usually a complication of respiratory disease, for example RDS or meconium aspiration syndrome (MAS) or congenital malformations, in which there is uneven ventilation, alveolar overdistension and air trapping, made worse in many cases by IPPV. Pneumothorax may occasionally result from direct injury to the lung, for example direct perforation by suction catheters or introducers passed through the ETT (Anderson and Chandra 1976; Vaughan et al. 1978) or by central venous catheter placement (Gabwell et al. 2000). Malposition of the ETT

is associated with an increased risk of pneumothorax (Niwas et al. 2007).

Components of ventilatory support have been incriminated in increasing the incidence of airleak. These include high levels of PEEP (Berg et al. 1975), but the data were not from a randomised study. A prolonged inflation time was also noted to be a risk factor (Primhak 1983), perhaps because of provocation of active expiration against the ventilator (Greenough 1988). The higher (50% versus 16%) incidence of airleak with an inspiratory:expiratory (I:E) ratio of >1.0:1 compared with an I:E ratio of <0.7:1 (Tarnow-Mordi et al. 1985) might also be explained by a similar mechanism. Both high peak inspiratory (Oh and Stern 1977; Greenough et al. 1984a) and mean airway pressures (MAPs) increased the incidence of airleaks (Tarnow-Mordi and Wilkinson 1985). Airleaks occur in babies who have started to exhale while the ventilator is still trying to inflate their lungs (active expiratory reflex) (Greenough et al. 1983).

Clinical features

Small pneumothoraces may be asymptomatic, but, when a large pneumothorax develops, all of the clinical features of respiratory distress may be present. In addition, with very large or tension pneumothoraces, the infant's overall condition usually deteriorates, often dramatically, with pallor, shock and deterioration in oxygenation. An increased resonance on percussion may be detected and there is a decrease in air entry on the affected side. A tension pneumothorax will result in a shift of the mediastinum and the position of the cardiac impulse; there is also abdominal distension due to displacement of the diaphragm and, with a right-sided pneumothorax, downward displacement of the liver. At the time of a pneumothorax, there is a marked increase in cerebral blood flow velocity, which correlates closely with the systemic haemodynamic changes (Hill et al. 1982). Pneumothorax is associated with haemorrhage into the germinal layer and ventricles of preterm infants. Increased levels of arginine vasopressin may also occur, resulting in fluid retention (Ch. 35.1).

Diagnosis

Continuous monitoring of the heart rate, BP and P_{aCO_2} will give warning of the baby's deterioration. Transillumination with an intense beam from a fiberoptic light is of considerable help in the preterm baby with a thin chest wall: abnormal air collections cause increased transmission of light on the involved side; however, PIE can give a similar appearance. The CXR remains the gold standard for diagnosing pneumothorax and should be done unless the infant's clinical condition makes emergency drainage mandatory. The diagnosis of a pneumothorax on the CXR is usually obvious, but rarely the appearance of either lobar emphysema or cystic adenomatoid malformation of the lung may resemble a pneumothorax (Liang et al. 2000). A small pneumothorax may only be recognised by a difference in radiolucency between the two lung fields (Fig. 27.16). A large pneumothorax will be associated with absent lung markings and a collapsed lung on the ipsilateral side (Fig. 27.17). A tension pneumothorax will be demonstrated by eversion of the diaphragm, bulging intercostal spaces and mediastinal shift (Fig. 27.18).

Ill, ventilated infants are usually nursed in the supine position and intrapleural air rises to lie retrosternally. Retrosternal air is best demonstrated by a horizontal-beam, lateral-view CXR (Fig. 27.19), which is also useful in demonstrating the position of the chest drain tip (see below; Fig. 27.20).

Fig. 27.16 Bilateral pneumothoraces. Note bulging at the intercostals' margins. The difference in the translucency of the two sides indicates that there is more free air on the left.

Prevention

The risk of pneumothorax can be reduced by administering surfactant (p. 459), by using the minimum ventilator pressure required (p. 517) and by abolishing the baby's active expiratory efforts.

Paralysis/sedation

Breathing out of phase with the ventilator during IPPV increases the incidence of pneumothorax (see above). Neuromuscular blocking agents should only be given selectively, that is, to infants who are actively expiring against the ventilator (Greenough et al. 1984b). Meta-analysis of six trials in which routine neuromuscular paralysis was compared with no routine paralysis demonstrated that no significant difference was found in airleak, mortality or BPD, but there was a significant reduction in IVH (Cools and Offringa 2009). In subgroup analysis of trials in which a selected group of infants with evidence of asynchronous respiratory effort were studied, there was a significant reduction in IVH of all grades and a trend towards less airleak (Cools and Offringa 2009). It was concluded, therefore, that for ventilated preterm infants with evidence of asynchronous respiratory effort, neuromuscular paralysis with pancuronium seems to have a favourable effect on IVH and possibly on pneumothorax. Active expiration may be difficult to detect clinically at slow rates; however, if a neonate's oxygenation fails to improve and obvious respiratory efforts continue as the ventilator rate is increased to 60–80/min, this identifies the majority of neonates with a persisting active respiratory pattern who are likely to benefit from paralysis (Greenough and Greenall 1988). Infants who receive neuromuscular blocking agents, such as pancuronium, require higher peak pressures when the first dose is given, to maintain oxygenation; ventilator rates should be reduced to <60/min to avoid gas trapping

Fig. 27.17 Large left-sided tension pneumothorax. Note that the non-compliant lung has only partially collapsed.

Fig. 27.18 Large right-sided tension pneumothorax with bulging over the midline and compression of the left lung.

(Hird et al. 1990). Other neuromuscular blocking agents include vecuronium, atracurium and cisatracurium. A single dose of vecuronium has been shown to reduce hypoxaemic episodes without impairing lung function (McEvoy et al. 2007).

Many clinicians prefer to avoid use of neuromuscular blocking agents and administer analgesics and/or sedatives to try and suppress respiratory activity, but also to minimise any discomfort felt by a ventilated baby (Ch. 25). Stress hormone levels have been demonstrated to be significantly related to the severity of illness and to fall with sedation (Barker and Rutter 1996). Administration of analgesics and/or sedatives, although having benefits, has not been demonstrated in randomised trials to reduce the pneumothorax rate (Lago et al. 1998) and they have side-effects. In a randomised trial (Orsini et al. 1996), fentanyl administration was associated with a reduction in stress markers, but no improvements in long-term outcome. Fentanyl can cause muscle rigidity and precipitate movement disorders, and withdrawal symptoms can occur. Plasma fentanyl clearance increases with maturity; thus gestational age should be

Fig. 27.19 Lateral chest X-ray with anterior collection of air. Only one chest drain is positioned to lie anteriorly; the other tip lies posteriorly and the pneumothorax has been inadequately drained.

Fig. 27.20 Lateral chest X-ray demonstrating a correctly anteriorly placed tip of a chest drain.

taken into account when prescribing fentanyl (Saarenmaa et al. 2000). Naloxone is an effective antidote to fentanyl. Morphine, compared with placebo, significantly reduced adrenaline (epinephrine) concentrations in ventilated neonates, but did not influence the occurrence of airleak (Quinn et al. 1993). Morphine does not appear to be associated with adverse effects on intelligence, motor function or behaviour at follow-up (MacGregor et al. 1998), but should be used with caution in prematurely born infants, because of its low clearance, which correlates with gestational age (Saarenmaa et al. 2000). In a large ($n = 898$) randomised trial (Bhandari et al. 2005), morphine infusion did not improve short-term pulmonary outcomes amongst ventilated infants and additional analgesia with morphine was associated with more airleaks and longer durations of high-frequency ventilation, nasal CPAP and oxygen therapy. In addition, secondary data analysis from that randomised trial demonstrated that use of morphine delayed the

attainment of full feeds, partly by delaying the start of feeding, although its use did not increase gastrointestinal complications (Menon et al. 2008). Diamorphine may be preferable to morphine, as in a randomised trial (Wood et al. 1998) both agents reduced the stress response to ventilation, but diamorphine had a more rapid onset of sedation and did not have morphine's tendency to increase hypotension. Midazolam is sedative in ventilated babies (Jacqz-Aigrain et al. 1994), but it does not influence the course of RDS and in high doses it causes respiratory suppression, hypotension and reduced cerebral blood flow. Long-term use can result in accumulation and an encephalopathic illness has been described. Midazolam is reversed by flumazenil. Midazolam is not as effective a sedative as chloral (Northern Neonatal Network 2000), but chloral can cause gastric irritation and its metabolite is hepatotoxic.

Modes of ventilation

High-frequency positive-pressure ventilation

Ventilating babies at rates of >60 /min rather than at 30–40/min reduced the incidence of airleaks (Bland et al. 1980; Heicher et al. 1981). Those data were subsequently confirmed by the results of two multicentre randomised studies (Octave Study Group 1991; Pohlandt et al. 1992). Meta-analysis of the results of the randomised trials (Greenough et al. 2008) demonstrated that the risk for airleak at the faster compared with the slower rate was significantly reduced. The most likely explanation for the reduction in airleak at the faster frequency was that spontaneous respiration synchronises with the ventilator at fast rates (Greenough et al. 1984a), whereas infants actively expire at slow rates. There have, however, been no randomised trials comparing different ventilator rates in infants routinely exposed to antenatal steroids and postnatal surfactant; whether fast rates are more effective than slow rates in preventing pneumothoraces in such a population remains unknown.

Patient-triggered ventilation

Meta-analysis of the results of randomised trials demonstrated that the incidence of airleak was not reduced by use of patient-triggered ventilation (PTV) (Greenough et al. 2008). During pressure support

ventilation (PSV), both the initiation and termination of ventilator inflation are determined by the infant's respiratory efforts. PSV does reduce the rate of asynchrony (Dimitriou et al. 1998a), but a reduction in the incidence of pneumothorax has not been reported.

High-frequency oscillation

Meta-analysis of the results of randomised trials has demonstrated that high-frequency oscillation (HFO) does not reduce the incidence of pneumothorax in preterm infants (Henderson-Smart et al. 2007). In a randomised trial (HiFO Study Group 1993), use of HFO was associated with a reduction in the incidence of pneumothorax, but this was at the expense of an increase in intracerebral haemorrhage (ICH).

Treatment

Asymptomatic pneumothoraces need no treatment, other than careful observation of the infant. In term infants with mild symptoms, a pneumothorax may respond to increasing the inspired oxygen concentration to 100%, which will favour resorption of the extra-alveolar gas; but this strategy should not be used in prematurely born infants at risk of ROP. Expectant management can be successful in infants who have relatively mild disease, i.e. on lower ventilatory settings and better blood gases (Litmanovitz and Carlo 2008). However, there is always a risk of the pneumothorax becoming a tension pneumothorax and there should be a low threshold for inserting a chest drain in a ventilated baby.

A pneumothorax must always be drained using a chest drain in symptomatic infants and those with tension pneumothoraces. If the infant is in extremis and there is no time for formal insertion of a chest drain, emergency drainage of a pneumothorax can be done by needle aspiration. A butterfly needle (18 G) should be used. This is then attached to a three-way tap, which is held under water in a small sterile container. The needle is inserted through the skin in the second intercostal space anteriorly, and then the skin and needle are moved sideways before advancing the needle through the underlying muscle; this reduces the likelihood of leaving an open needle track for entry of air once the needle has been removed. Care must be taken not to remove too much air by needle aspiration, as the needle might then tear the expanding lung. Following emergency drainage, a chest tube should be inserted (Ch. 44).

Insertion of a chest tube (10–14 FG) should be performed under local anaesthesia through either the second intercostal space just lateral to the midclavicular line or the sixth space in the midaxillary line (see Ch. 44). The tip of the chest tube should lie retrosternally to achieve the most effective drainage. A retrospective review of 149 cases of chest drain placement (Allen et al. 1981) revealed that inserting the chest drain through the anterior chest wall achieved retrosternal positioning in 85% of occasions compared with only 47% inserted through the lateral chest wall. The lateral site, however, is preferred for cosmetic reasons, as any resultant scar is less obvious. Retrosternal placement of the chest tube tip should be confirmed by CXR (Chs. 43, 44); a second drain is only infrequently required to ensure complete drainage if the first drain has been appropriately sited.

Complications of malpositioned chest tubes include traumatising of the thoracic duct resulting in a chylothorax, cardiac tamponade due to a haemorrhagic pericardial effusion and phrenic nerve injury; the latter complication is more likely if the drainage tube is positioned deep in the chest (Williams et al. 2003). Once inserted, the tube should be connected to an underwater seal drain with suction applied at a level of 5–10 cmH₂O. Heimlich valves are useful during transport, but can become blocked and so fail to

operate if left in situ for any length of time. Once a chest drain has been inserted, it should be left in situ for at least a further 24 hours after it has ceased bubbling. The chest tube should then be clamped for a further few hours and only removed if no pleural air accumulates. Pneumothoraces persisting for an average of 10 days may respond to fibrin glue, but this treatment has been reported to have significant risks (Sarkar et al. 2003).

After drainage of an uncomplicated pneumothorax, a baby not on IPPV usually improves rapidly. In a ventilated, very prematurely born baby, a pneumothorax often precipitates a serious deterioration in condition, with the development of a large intracerebral bleed.

Bronchopleural fistula

A large tear in the pleural surface of the lung, a bronchopleural fistula, may not close with conventional tube drainage of the pneumothorax. Alternative strategies are surgical closure at thoracotomy (Grosfeld et al. 1980), selective bronchial intubation (see below) (Al-Nishi et al. 1994) or instillation of fibrin glue into the pleural space (Berger and Gilhooly 1993).

Prognosis

The mortality, although not the incidence, varies with birthweight and is in general double that of babies who have RDS but no airleak. If a parenchymal haemorrhage occurs in association with a pneumothorax (Ch. 40.5), this has a detrimental effect on neurological outcome.

Pulmonary interstitial emphysema

Aetiology

PIE is gas trapped within the perivascular sheaths of the lung. In the surfactant-deficient lung of the preterm infant (Plenat et al. 1978), rupture of the small airways occurs distal to the termination of their fascial sheath, and air dissects into the interstitium. PIE occurs mainly in neonates with RDS (Campbell 1970), but has been less frequently reported in infants with aspiration syndromes or sepsis. PIE is associated with positive-pressure ventilation, high peak inspiratory pressures and malpositioned ETTs (Hart et al. 1983; Greenough et al. 1984a). It has rarely been described in spontaneously breathing infants (Dembinski et al. 2002). PIE may be lobar in distribution, but more commonly involves both lungs. It frequently occurs with either a pneumothorax or pneumomediastinum.

Incidence

There is an inverse relationship between the incidence of PIE and birthweight (Hart et al. 1983).

Pathophysiology

In infants with PIE, the trapped gas reduces pulmonary perfusion by compressing the vessels and interferes with ventilation. As a result, there is profound hypoxaemia combined with carbon dioxide retention.

Presentation

PIE is found on the CXR of a severely ill neonate carried out either on a routine basis or because the baby's condition was deteriorating.

Fig. 27.21 Bilateral pulmonary interstitial emphysema.

Fig. 27.22 Gross pulmonary interstitial emphysema (PIE) of the right lung with overdilation and downward displacement of the diaphragm and moderately severe PIE of the left lung.

Fig. 27.23 Severe pulmonary interstitial emphysema of the right lung with mediastinal shift and compression of the left lung.

Fig. 27.24 Pulmonary interstitial emphysema of the right lung with gross cystic changes in the right middle lobe compressing the right lower lobe and left lung.

Diagnosis

Transillumination of the chest with diffuse PIE will give the same appearance as a large pneumothorax. The CXR, however, is diagnostic, demonstrating hyperinflation and a characteristic cystic appearance, which may be diffuse, multiple, small, non-confluent, cystic radiolucencies (Figs 27.21 and 27.22), which may be unilateral (Fig. 27.23); at a later stage, large bullae may appear (Fig. 27.24). The appearance may be confused with lobar emphysema or with cystic adenomatoid malformation of the lung.

Treatment

Affected babies usually have severe RDS and/or sepsis; their ventilator management is particularly difficult. For both generalised and

localised disease, ventilator pressures should be kept at the minimum compatible with acceptable gases ($P_{aO_2} < 6-7$ kPa (45–52 mmHg), pH > 7.25); the baby should be paralysed to minimise the risk of extension of the airleaks. Withdrawal of PEEP may result in disappearance of the PIE (Leonidas *et al.* 1975).

Generalised PIE may respond to increasing the ventilator rate to 100–120/min (Ng and Easa 1979), in that the number of babies who progress to pneumothorax may be reduced, but there were no other advantages. Indeed, in one series (Greenough *et al.* 1984a), the severity of the PIE increased, possibly because of the absence of a pneumothorax decompressing the interstitial emphysema. Transfer from conventional ventilators to high-frequency jet ventilation (HFJV) (Pokora *et al.* 1983; Boros *et al.* 1985), high-frequency flow interruption (Frantz *et al.* 1983) or oscillation (Clark *et al.* 1986)

Fig. 27.25 Endotracheal tube inserted into the right main bronchus with resultant collapse of the left lung and right upper lobe.

has improved oxygenation in some infants with severe respiratory failure due to PIE, but a randomised controlled trial failed to show that HFO had benefit in PIE (HiFO Study Group 1993). HFJV has been reported in a randomised trial to be more successful support than rapid-rate conventional ventilation (Keszler et al. 1991); survival and the incidence of BPD, GMH/IVH, PDA, airway obstruction and airleak, however, were similar in the two groups.

The conservative ventilatory management outlined above for generalised PIE should also be tried for localised disease and is often successful. In addition, in localised PIE, placing the infant with the hyperinflated lung dependent in the lateral decubitus position at all times can result in partial or complete atelectasis of the desired segments (Cohen et al. 1984; Swingle et al. 1984). In this position, the upper 'good' lung receives a greater proportion of the ventilation (Heaf et al. 1983); the affected dependent lung is underventilated and hence decompresses. Selective bronchial intubation may also be useful. As soon as the affected lung is bypassed, it becomes atelectatic (Fig. 27.25). If selective intubation is maintained for 24–48 hours, when the affected lung is reventilated the PIE does not usually recur (Brooks et al. 1977; Chan and Greenough 1992; Al-Nishi et al. 1994). This technique is more useful if the left lung is affected, as selective intubation of the right main bronchus is easier to perform. It may be necessary to support the infant on high-frequency oscillatory ventilation (HFOV) to maintain adequate blood gases during selective intubation (Rettwitz-Volk et al. 1993). The collections may persist and compress the adjacent normal lung parenchyma, causing a sudden deterioration in the infant's condition. Resection of the affected area may be required to alleviate the respiratory distress.

Prognosis

The incidence of BPD is greatly increased following diffuse PIE (p. 490) (Stahlman et al. 1979; Yu et al. 1983) and radiologically the changes of PIE may merge imperceptibly into those of BPD. The mortality from diffuse PIE is high, but studies reporting outcome generally predate routine use of antenatal steroids and postnatal surfactant (Hart et al. 1983; Greenough et al. 1984a; Morisot et al. 1990).

Fig. 27.26 Left-sided pneumomediastinum (between the arrows and the heart border).

Pneumomediastinum

Pneumomediastinum occurs in approximately 2.5 per 1000 live-births, in those babies with gas trapping associated with RDS, pneumonia, MAS and mechanical ventilation.

Presentation

An isolated pneumomediastinum may be asymptomatic or the infant may have mild respiratory distress; it only rarely causes severe symptoms. The sternum may appear bowed and the heart sounds muffled. Mediastinal shift rarely occurs. Air may track up into the soft tissues of the neck, but this is uncommon. Pneumomediastinum often coexists with multiple airleaks, including PIE and pneumothorax, in severely ill, ventilated babies (Fig. 27.26).

Diagnosis

This is made on the CXR (Fig. 27.26), as a halo of air adjacent to the borders of the heart, and on lateral view it produces marked retrosternal hyperlucency. The mediastinal gas may elevate the thymus away from the pericardium, resulting in a crescentic configuration resembling a spinnaker sail (Moseley 1960).

Treatment

An isolated pneumomediastinum is often asymptomatic and in general requires no treatment. It is very difficult to drain a pneumomediastinum, as the gas is collected in multiple independent lobules. Relatively successful attempts have been made, however, with multiple needling and tube drainage (Taylor et al. 1993). In term infants, use of a high inspired oxygen concentration will be associated with resorption of the extra-alveolar air, but this should not be attempted in preterm infants at risk from ROP.

Pneumopericardium

A pneumopericardium usually causes cardiac tamponade with sudden hypotension, bradycardia and cyanosis. The heart sounds are muffled, but a friction rub is rarely audible. The signs may be

Fig. 27.27 Pneumopericardium: (A) anteroposterior view; (B) lateral view. There is also a right pneumothorax.

confused with those of a tension pneumothorax, but the CXR is diagnostic (Fig. 27.27). It is usually accompanied by other major airleaks such as pneumomediastinum, widespread PIE or tension pneumothorax.

Aetiology

Pneumopericardium rarely occurs spontaneously (Itani and Mikati 1998) or in babies supported by CPAP (Heckman et al. 1998). The majority of cases occur in ventilated, prematurely born babies. Its frequent association with PIE and pneumomediastinum suggests that the gas enters the pericardium through a defect in the pericardial sac, probably at the pericardial reflection near the ostia of the pulmonary veins.

Diagnosis

The CXR demonstrates gas completely surrounding the heart (Fig. 27.27), outlining the base of the great vessels and contained within the pericardium. Gas can be seen inferior to the diaphragmatic surface of the heart, differentiating this abnormality from a pneumomediastinum in which the mediastinal gas is limited inferiorly by the attachment of the mediastinal pleura to the central tendon of the diaphragm. In a haemodynamically significant pneumopericardium, the transverse diameter of the heart is significantly reduced.

Treatment

A conservative approach can be adopted for small asymptomatic lesions. All symptomatic pneumopericardia should be drained immediately by direct pericardial tap via the subxiphoid route. The BP should be monitored continuously, and the tap repeated if bradycardia or hypotension recurs. Catheter drainage may be necessary if the pericardial air reaccumulates.

Prognosis

The mortality rate for symptomatic pneumopericardium is between 80% and 90% (Hook et al. 1995) and many survivors have neurological sequelae.

Pneumoperitoneum

This may result from perforation of the gut, but may also be caused by air dissecting from the chest through the diaphragmatic foramina into the peritoneum (Aranda et al. 1972) (Fig. 27.28), particularly in ventilated babies who already have a pneumothorax and a pneumomediastinum. In some cases, the gas localises in the connective tissue on the posterior wall of the abdomen, a pneumoretroperitoneum (Karlłowicz 1994).

Diagnosis

If the pneumoperitoneum is large, the diagnosis can be made from the anteroposterior X-ray (Fig. 27.29). For smaller leaks, a horizontal-beam lateral or right lateral X-ray is required (Fig. 27.30). Rupture of the bowel, usually due to NEC, can generally be excluded by the absence of a history of gastrointestinal disease, in particular bloody stools or intestinal obstruction, and a normal gut gas pattern on erect abdominal X-ray. If there is still doubt, differentiating a pneumoperitoneum caused by transdiaphragmatic air dissection from one due to perforated bowel can be made by measuring the P_{O_2} of aspirated intraperitoneal gas (Vanhaesebrouck et al. 1989). In ventilator-induced pneumoperitoneum, the intraperitoneal P_{O_2} is very high, reflecting the PA_{O_2} , whereas the P_{O_2} of a surgical pneumoperitoneum is similar to that of room air or lower.

Treatment

If the abdomen is not under sufficient tension to cause respiratory embarrassment, then no treatment is necessary. If there is tension,

Fig. 27.28 Pneumoperitoneum associated with gross pulmonary interstitial emphysema.

the peritoneum should be drained either by needle aspiration or by inserting a drainage tube.

Systemic air embolism

This is a rare complication of IPPV. Affected infants are usually premature, have severe pulmonary insufficiency necessitating very high ventilator pressures (>40 cmH₂O) and the majority (94%) have other airleaks (Lee and Tanswell 1989). This condition has, however, been reported in infants supported by CPAP (Wong et al. 1997). It is associated with a sudden and catastrophic deterioration in the baby's condition, with pallor or cyanosis, hypotension and bizarre ECG irregularities.

Pathogenesis

Gas embolism results from alveolar–capillary or bronchovenous fistulae, which have been demonstrated by barium studies at autopsy. Such communications are more likely to occur in airleak syndromes, but may also follow trauma to the lung. Laceration of lung tissue favours reversal of the intrabronchial pressure–pulmonary venous pressure gradient, thereby increasing the risk of pulmonary vascular air embolism.

Diagnosis

On the CXR, gas can be seen in the systemic and pulmonary arteries and veins (Fig. 27.31). Gas can be withdrawn from the umbilical venous or arterial catheters, and this has been observed in over half the reported cases.

Fig. 27.29 Pneumoperitoneum due to gastrointestinal perforation. (A) Anteroposterior view shows the classic 'football' sign. (B) The lateral X-ray of the same infant shows a large collection of free air above the liver.

Treatment

Early withdrawal of air from the UAC may be of benefit, particularly if the leak is small or has been introduced through an intra-vascular line.

Prognosis

This condition is usually fatal (Lee and Tanswell 1989).

Subcutaneous emphysema

This condition, with air tracking into the neck or other subcutaneous tissues, is usually associated with a pneumomediastinum. It requires no treatment. A localised subcutaneous collection of air

Fig. 27.30 Pneumoperitoneum indicated on the anteroposterior view by a small amount of non-anatomical air to the right of the vertebral column.

Fig. 27.31 Postmortem X-ray of a baby who died from systemic air embolism. Gas can be seen (black arrows) within the heart and in the great vessels in the neck (white arrows).

under tension – a bronchocutaneous fistula – has been described (Bailldam et al. 1993).

Persistent pulmonary hypertension of the newborn

The dominant pathophysiological feature of PPHN is a high PAP. This condition has been called persistent fetal circulation, but this term should be avoided, as one of the characteristic features of the fetal circulation, the high-flow, low-resistance circuit through the placenta, is missing.

Definition and classification

Persistent fetal circulation syndrome was first used by Gersony et al. (1969) to describe babies who had a structurally normal heart, but large right-to-left shunts at atrial and ductal levels secondary to pulmonary hypertension. It is now understood that PPHN is the common endpoint of several different pathophysiological mechanisms. PPHN is present when an infant with an echocardiographically confirmed structurally normal heart has:

- severe hypoxaemia, usually a P_{aO_2} 5–6 kPa (37.5–45 mmHg) in an F_{iO_2} of 1.0 and IPPV if necessary
- mild lung disease, but the hypoxaemia is disproportionately severe for the radiological, clinical and acid–base abnormalities
- evidence of a right-to-left ductal shunt (usually a P_{aO_2} in the distal aortic (UAC) blood 1–2 kPa (7.5–15 mmHg) lower than simultaneous preductal (right radial artery) P_{aO_2} estimation); in the absence of a ductal shunt; a large shunt may be demonstrated echocardiographically at the foramen ovale (Valdes-Cruz et al. 1981).

There are a number of distinct syndromes which can result in a baby developing PPHN:

- Primary PPHN or PPHN in the presence of mild neonatal lung disease. Those with primary disease are the babies originally described by Gersony et al. (1969) who are profoundly hypoxic but have no clinical or autopsy evidence of lung disease. This entity merges into PPHN in babies who have disproportionately severe hypoxaemia from what appears clinically, radiologically and on P_{aCO_2} measurements to be mild parenchymal lung disease. There is now considerable evidence to suggest that this entity is due to excessive muscularisation of the pulmonary arterial system starting in the antenatal period (see below), perhaps aggravated by perinatal asphyxia (Reece et al. 1987).
- PPHN secondary to severe perinatal asphyxia. In these babies, hypoxia and acidaemia, both of which are powerful pulmonary artery constrictors (Lyrene and Philips 1984), prevent the normal postnatal changes in circulation. The tendency to PPHN may be increased in such neonates by similar structural changes in the vasculature to those outlined above and the large right-to-left shunt may be aggravated by systemic hypotension secondary to postasphyxial myocardial damage (Caball et al. 1980).
- PPHN secondary to infection. This particularly severe form of the disease, characteristically associated with GBS sepsis, is probably due to the release of vasoactive substances.
- PPHN secondary to pulmonary hypoplasia. This is characteristic of neonates with diaphragmatic hernia, and is due to the abnormal development and reduced cross-sectional area of the pulmonary vasculature (Geggel and Reid 1984).

- PPHN secondary to drug therapy. This has been reported after the use of prostaglandin synthetase inhibitors before delivery. One survey demonstrated that mothers of inborn term babies with PPHN were 9.6 times more likely to have taken aspirin in pregnancy and 17.5 times more likely to have taken other prostaglandin synthetase inhibitor drugs (van Marter et al. 1996). These drugs, either by a direct effect on the pulmonary vasculature or by closing the fetal ductus, cause fetal pulmonary hypertension which persists postnatally (Levin et al. 1979; Turner and Levin 1984). It is probably the result of changes in the pulmonary arterial musculature similar to those reported in primary PPHN (Levin et al. 1978) (Fig. 27.32). Administration of ibuprofen, a cyclo-oxygenase inhibitor, in the first 6 hours after birth has been associated with the development of pulmonary hypertension (Gournay et al. 2002).
- PPHN secondary to alveolar capillary dysplasia. Several reports have appeared of babies with clinical PPHN in whom, at postmortem, there appeared to be misalignment of the pulmonary vessels and poor apposition of the vessels to the alveoli (Cater et al. 1989). This condition is fatal and does not respond to extracorporeal membrane oxygenation (ECMO) (Chelliah et al. 1995).
- PPHN secondary to congenital heart disease. Conditions that obstruct the venous outflow from the lungs or cause myocardial failure can cause pulmonary hypertension and/or marked right-to-left shunting with hypoxaemia. They are considered in detail in Chapter 28.
- Iatrogenic PPHN secondary to overventilation (p. 517).

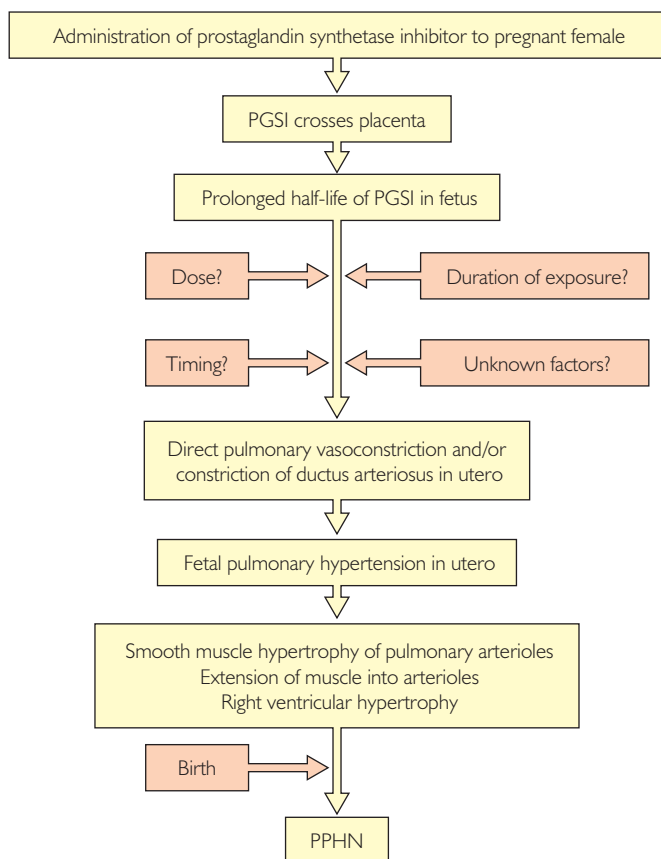

Fig. 27.32 Mechanism of drug-induced persistent pulmonary hypertension of the newborn. PGSI, prostaglandin synthetase inhibitor. (Reproduced from Turner and Levin (1984).)

Pathophysiology

The pathognomonic feature of this condition is the presence of pulmonary hypertension, producing right-to-left shunts at the level of the ductus arteriosus and the foramen ovale (Duara and Fox 1986; Skinner et al. 1996). The comparatively small difference between pre- and postductal P_{aO_2} levels, rarely greater than 2–3 kPa (15–21 mmHg), however, suggests that only a small component of the shunt occurs at duct level and the majority is through the foramen ovale (Valdes-Cruz et al. 1981). PAP is at or above systemic levels. Skinner et al. (1996) have shown that a marked reduction in left ventricular function is a significant marker of severe disease.

Abnormal pulmonary vasculature

Infants with PPHN have abnormal pulmonary vascular reactivity, structure and/or growth. In postmortem studies on babies with PPHN, virtually all secondary to meconium inhalation, the muscularity of the pulmonary arteries is markedly increased (Murphy et al. 1981, 1984). Not only is the amount of muscle in the vessel wall increased, but also the muscle extends into vessels surrounding the alveoli, whereas in the normal baby muscular pulmonary arteries rarely extend past the terminal bronchiole. The exact intrauterine events that increase pulmonary vascular reactivity and impair structure are poorly understood. Impaired vascular epidermal growth factor (VEGF) signalling, however, can cause fetal pulmonary hypertension with structural remodelling, right ventricular hypertrophy and impaired pulmonary vasodilation in experimental models (Grover et al. 2003). Chronic intrauterine pulmonary hypertension can markedly decrease lung VEGF expression; selective inhibition of VEGF mimics the structural and physiological changes of experimental PPHN (Grover et al. 2003). Babies with PPHN have lower blood VEGF levels than controls (Lassus et al. 2001). Postnatally, sustained pulmonary hypertension rapidly accelerates pulmonary vascular injury, with aggressive smooth-muscle proliferation and remodelling. Initially the effects of hypertension are at least partially offset by release of endogenous vasodilators, but this may not be sustained (Abman et al. 1996).

Vasoactive agents

NO is a potent pulmonary vasodilator, active in the transition of the circulation at birth (p. 450). A significant rise in pulmonary blood flow at birth is related to the acute release of NO; vasodilation occurs through cGMP kinase-mediated stimulation of K^+ channels (Cornfield et al. 1996). Other vasodilator products, including prostaglandin (PG) I_2 , also modulate changes in pulmonary vascular tone at birth. NO modulates PGI_2 activity in the perinatal lung (Zenge et al. 2001). Adenosine release may also contribute to the fall in pulmonary vascular resistance; this may be through enhanced production of NO (Konduri and Mital 2000).

Endothelin-1 is a potent pulmonary vasoconstrictor; the plasma level is raised in neonates with hypoxia (Kourembanas et al. 1991) and severe PPHN (Rosenberg et al. 1993; Kumar et al. 1996). Increased circulating levels of endothelin-1 mediate in part GBS-induced pulmonary hypertension (Navarrete et al. 2003). Raised levels of the constrictor leukotrienes LTC_4 and LTD_4 have been found in the blood of some, but not all, neonates with PPHN when compared with ventilated neonates without this complication; the levels fall with successful therapy (Stenmark et al. 1983; Hammerman et al. 1987; Kühl et al. 1989; Dobyns et al. 1994). In the PPHN accompanying sepsis due to GBS or other organisms (Shankran et al. 1982; Gibson et al. 1988; Waites et al. 1989),

including viruses (Toce and Keenan 1988), there is initial severe arterial spasm followed by increased vascular permeability and an increased lung fluid content and lymph flow (Rojas et al. 1983; Sandberg et al. 1987a; Philips et al. 1988). In these babies it is thought that thromboxane A_2 (Runkle et al. 1984; Hammerman et al. 1987; Gibson et al. 1988) is responsible and that it has its effect without affecting the morphometry of the pulmonary vasculature (Barefield et al. 1994). In animal models, PPHN, but not the haematological features of GBS sepsis, can be prevented by treatment with drugs which inhibit thromboxane A_2 synthesis, such as indometacin (Runkle et al. 1984), and reversed by intravenous infusion of the vasodilator prostaglandin PGE_2 or isoprenaline (Brigham et al. 1988; Crowley et al. 1991). The increased capillary permeability in sepsis-induced PPHN appears to be due to the action of bacterial endotoxins sequestering white cells in the lungs (Rojas and Stahlman 1984; Sandberg et al. 1987a), where they release vasoactive agents such as tumour necrosis factor. There is an additional effect of thromboxane A_2 since, as with the short-term effects on the pulmonary vasculature, long-term effects can be mitigated by the use of indometacin.

Vascular hypoplasia

The PPHN of diaphragmatic hernia and other conditions associated with pulmonary hypoplasia is due to a reduction in the number of intralobar arteries and their increased muscularity (Gegge et al. 1985).

Blood gas changes/asphyxia

A fall in pH causes pulmonary vasoconstriction in experimental animals (Rudolph and Yuan 1966; Rudolph 1977), and hypoxia is a potent vasoconstrictor (Lyrene and Philips 1984). Neonatal pulmonary vasculature is extremely sensitive to changes in pH, P_{aO_2} and P_{aCO_2} (Cassin et al. 1964). Therefore, perinatal and postnatal hypoxaemia and metabolic or respiratory acidemia can cause marked pulmonary arterial spasm, pulmonary hypertension, a large right-to-left shunt and PPHN, particularly in babies with prenatal pulmonary arterial muscular hypertrophy.

Polycythaemia

A rise in haematocrit in experimental animals causes pulmonary hypertension. The factors involved, however, are not clear, since a rise in pulmonary vascular resistance is not seen if fetal blood as opposed to adult blood is used to raise the haematocrit (Fouron et al. 1985) and polycythaemia is not a consistent feature of neonates with PPHN (Fox and Duara 1983).

Heredity

Familial cases have been reported.

Clinical features

In babies with primary PPHN, the presentation is often subtle and may mimic that of cyanotic congenital heart disease. Babies with primary PPHN virtually always present within 12 hours of birth and very rarely after 24 hours. In PPHN which is secondary to pre-existing lung disease, the clinical features will be those of GBS sepsis (Ch. 39.2), RDS (p. 476) or MAS (p. 503), together with the cyanosis of severe PPHN. Secondary effects from the hypoxia, such as acidemia and hypotension, may be present. The age at diagnosis still depends on the underlying problem and its severity. In GBS

infection (Ch. 39.2), severe asphyxia (Ch. 40.4) and congenital diaphragmatic hernia (CDH; p. 593), PPHN will appear within 6 hours of birth in a critically ill neonate.

The baby remains cyanosed even when high oxygen concentrations are administered by IPPV. Respiratory distress, however, is often mild. The respiratory rate is usually increased to 60–100/min; the higher rates are seen in term babies. Retraction is mild, grunting rare and the air entry is normal. The heart rate is normal or slightly increased. All pulses, including the femorals, are normal. The first heart sound is normal, but the second is commonly single and loud because of the rise in PAP. There is a right parasternal heave and a soft systolic murmur may be heard, signifying tricuspid incompetence or, occasionally, mitral incompetence. Heart failure is not usually present, but the infant may be hypotensive. Examination of the abdomen, genitourinary system and the central nervous system is usually normal in the absence of predisposing factors such as sepsis or asphyxia.

Differential diagnosis

Cyanotic congenital heart disease, which presents in the first 12 hours, is usually a severe form, with heart failure, distinctive murmurs and obvious changes on the CXR and ECG. In PPHN, however, the CXR and ECG are often within the normal limits, and the findings on examination of the cardiovascular system are comparatively subtle (see above).

Echocardiography will establish the normal cardiac anatomy in PPHN. The response to ventilation with 100% oxygen may differentiate PPHN from cyanotic congenital heart disease (Fox and Duara 1983). In the former, the P_{aO_2} will usually increase to >13 kPa (100 mmHg), whereas in cyanotic heart disease it will not rise above 5–6 kPa (37.5–45 mmHg). Not all neonates with PPHN, especially those with sepsis and CDH, however, respond in this way.

Investigations

Haematological and biochemical

Thrombocytopenia has been reported in severe cases (Segal et al. 1980); it may be a manifestation of abnormal prostaglandin activation.

Blood gases

In both primary and secondary PPHN, maximal P_{aO_2} values of 6 kPa (45 mmHg) are characteristic, often with a difference of at least 1–2 kPa (7.5–15 mmHg) between preductal and postductal P_{aO_2} (Ch. 19). At diagnosis there may be a metabolic acidemia, but respiratory acidemia, by definition, is unusual. Metabolic acidemia can be controlled by an initial infusion of base, followed by BP support and maintaining the haematocrit above 40%. A resistant acidosis is a feature of either the terminal stages of PPHN or some other underlying problem – in particular, overwhelming sepsis.

Chest X-ray

In secondary PPHN, the X-ray will be that of the underlying lung disease, although, by definition, the appearance will be less severe than anticipated for the severity of the hypoxaemia. In primary PPHN, the CXR changes are often minimal (Fig. 27.33); there may be a mild non-specific increase in lung markings, but little else is noted.

Fig. 27.33 Chest X-ray of an infant with primary persistent pulmonary hypertension of the newborn with absence of lung field markings.

Electrocardiogram

Various ECG changes have been reported in neonates with PPHN. The ECG may be normal, or more typically shows changes of right axis deviation, right atrial enlargement and right ventricular hypertrophy and overload (Henry 1984). In babies who develop PPHN following severe asphyxia, the ECG may show the changes of sub-endocardial ischaemia (Appendix 3).

Echocardiography

Echocardiography is an essential investigation in suspected PPHN, and if the skill is not available a cyanosed baby requires transfer to a centre where this can be done. Firstly, and most importantly, it will exclude the various forms of cyanotic congenital heart disease by showing a normal cardiac anatomy. Secondly, pulmonary hypertension, right-to-left shunting at the ductal and foramen ovale level and ventricular function can be assessed (Skinner et al. 1996).

Bacteriology

PPHN can be secondary to sepsis; thus it is important that the infant is screened for infection (Ch. 39.2).

Treatment

The treatment of PPHN can be divided into two components: that of the hypoxaemia and PPHN and that of the coexisting lung disease, which is covered elsewhere.

Minimal handling

It is important to adhere to the 'minimal handling' maxim. Slight disturbance, for example turning the baby or taking the baby's temperature, may precipitate severe hypoxaemia, and interventions such as ETT suctioning or physiotherapy can have devastating effects. Monitoring must therefore be continuous and interference with the baby reduced to an absolute minimum. ETT suctioning should be carried out only when essential to maintain ETT patency; chest physiotherapy is contraindicated.

Blood pressure and blood volume

The size of the right-to-left shunt is in part dependent on the systemic BP (see above); thus, in babies born at term, the systemic BP should be maintained at a mean of at least 40 mmHg, with a systolic of 50 mmHg. Aggressive therapy should be used to achieve an appropriate systemic BP, including volume challenges and, particularly, administration of inotropes. The haemoglobin level should be kept greater than 13 g/dl (PCV 40%) in order to maximise oxygen transport to the tissues. If polycythaemia (central PCV <70–75%) is present, the existence of PPHN is one of the situations in which a dilutional exchange transfusion is justified.

Coagulation disorders

If present, these should be corrected by appropriate factor replacement.

Fluid and electrolyte balance

Electrolyte abnormalities and hypoglycaemia must be corrected and pH and base deficit kept within normal limits by use of THAM or bicarbonate as appropriate. Urine output must be carefully monitored.

Antibiotics

Broad-spectrum antibiotic cover should be given to all babies with PPHN.

Respiratory support

Once a baby's P_{aO_2} falls below 5–6 kPa (37–45 mmHg) in 70% oxygen, the baby should be ventilated. Sufficient peak pressure should be used to achieve a P_{aCO_2} of not greater than 4.8–5.5 kPa (35–40 mmHg) and a pH <7.30. The inspired oxygen concentration should be increased as necessary to achieve a P_{aO_2} of at least 8–9 kPa (56–63 mmHg). For the full-term baby prone to fight the ventilator, neuromuscular blocking agents should be used; in this situation there are theoretical reasons for preferring D-tubocurarine to pancuronium (Hutchinson and Yu 1980).

PPHN unresponsive to conservative treatment

Alkalinisation

This was described first by Peckham and Fox (1978). Reduction of the P_{aCO_2} to 2.5–3.5 kPa (19–26 mmHg) and elevation of the pH to 7.55–7.60 resulted in a rise in P_{aO_2} . Hyperventilation is no longer advocated, because a P_{aCO_2} of 2.5–3.5 kPa (19–26 mmHg) results in a 50% reduction of cerebral blood flow, which could cause cerebral ischaemia. Although in babies born at term no long-term adverse sequelae have been described, hypocapnia in preterm babies has been linked to PVL (Griesen et al. 1987; Ikonen et al. 1992) and marked hypocapnia (2.5 kPa (19 mmHg)) may reduce cardiac output (Cartwright et al. 1984). Hyperventilation, via barotrauma, may also result in airleaks (Fox 1982) and BPD (Fox and Duara 1983; Beck 1985). In addition, persisting hypocapnic alkalaeia markedly increases the hypoxic reactivity of the pulmonary vasculature, thus tending to perpetuate the pathophysiology of PPHN (Gordon et al. 1993).

High-frequency oscillation: jet ventilation

Anecdotally, these forms of respiratory support have been associated with improvements in oxygenation (Kohelet et al. 1988; Spitzer et al. 1988; Varnholt et al. 1992).

Extracorporeal membrane oxygenation

ECMO is an effective rescue therapy for infants with PPHN (UK Collaborative ECMO Trial Group 1996) (see p. 525).

Vasodilator drugs

Tolazoline

Tolazoline is no longer the drug of choice for PPHN. Between 25% and 50% of babies with primary PPHN or PPHN secondary to RDS or MAS respond to this agent, but the effects on the systemic circulation are at least as great as those on the pulmonary vasculature, and side-effects, including significant hypotension, are common. Other side-effects have been reported and include renal failure and gastrointestinal haemorrhage (Ward 1984). Side-effects may be minimised by a dilute, slow infusion (Nuntnarumit et al. 2002), but we recommend that iNO be considered first.

Prostacyclin

Prostacyclin (PGI_2) affects vascular tone by increasing cAMP levels. This agent, in doses of 5–40 ng/kg/min, is an effective pulmonary vasodilator, but has a wide list of side-effects (Petros 1995).

Endotracheal administration of tolazoline (Curtis et al. 1993) or PGI_2 (Kelly et al. 2002) can cause selective vasodilation. Inhalation of PGI_2 in animals and babies has been shown to be at least as effective as the parenteral preparation, with fewer side-effects, and to cause an equivalent response to iNO (Bindl et al. 1994; Zobel et al. 1995). High doses of aerosolised PGI_2 , however, could spill over into the systemic circulation, and thus the magnitude of the dose administered is critical if this therapy is to be a selective pulmonary vasodilator.

Iloprost is a PGI_2 analogue; it has advantages over PGI_2 in that it has a longer half-life and does not need to be dissolved in an alkaline solution, which is potentially damaging to the lung. There are case reports of it improving oxygenation in infants poorly responsive to iNO (de Luca et al. 2007).

Magnesium sulphate

As a loading dose of 200 mg/kg followed by an infusion of 20–100 mg/kg/h, it is effective (Tolsa et al. 1995; Wu et al. 1995) but less so and with more side-effects than iNO (Ryan et al. 1994). During magnesium therapy, levels must be carefully monitored, as hypermagnesaemia can cause sedation, muscle relaxation, hyporeflexia, and calcium and potassium disturbances. Magnesium sulphate has not been assessed in appropriately designed randomised trials; its use cannot therefore be recommended (Ho and Rasa 2007).

Inhaled nitric oxide

NO is a vasodilator substance that relaxes vascular smooth muscle. It is synthesised in the endothelial cells from L-arginine and oxygen (Edwards 1995). Neonates who suffer from PPHN may have low levels of arginine (Vosatka et al. 1994), but this is not a universal finding (Kavvadia et al. 1999). NO diffuses into the smooth-muscle cells, where it activates guanylate cyclase to increase 3,5-GMP and hence produces relaxation of the smooth muscles. When NO is inhaled, it diffuses across the alveolar capillary membrane and activates guanylate cyclase in the pulmonary arteriolar smooth muscle. The resulting increase in cGMP causes smooth-muscle relaxation. NO then binds rapidly to haemoglobin; once bound, it is inactivated and therefore produces no systemic effects.

Clinical studies. Since the preliminary studies of Kinsella et al. (1992) and Roberts et al. (1992), there have been many reports of the benefit of NO in PPHN. The efficacy of iNO is improved if it is

combined with a strategy to improve lung volume (Wilcox et al. 1994; Kinsella and Abman 1995). iNO can be delivered with either HFJV or HFOV (Coates et al. 2008). In infants with PPHN and severe lung disease, the combination of HFOV and iNO is better than iNO or HFOV alone (Kinsella et al. 1997). Even in patients with moderate PPHN, iNO can increase arterial oxygenation and reduce the amount of ventilatory support required (Sadiq et al. 2003). Not all term babies, however, respond: a poor response has been seen in those with severe parenchymal disease, systemic hypotension and myocardial dysfunction, as well as in those with structural pulmonary abnormalities, for example infants with pulmonary hypoplasia or dysplasia, who can develop a sustained dependence on iNO (Goldman et al. 1996).

In term-born babies, meta-analysis of the results of nine randomised trials demonstrated that use of iNO was associated with an improvement in oxygenation and a reduction in the combined outcome of death or need for ECMO; the effect was due to a reduction in the need for ECMO (Soll 2009a). No excess of adverse neurodevelopmental outcomes has been demonstrated in babies exposed to iNO in randomised trials (Neonatal Inhaled Nitric Oxide Study Group 2000; Field et al. 2007; Konduri et al. 2007). No significant long-term benefits of iNO have been demonstrated in babies with CDH and they have a higher incidence of sensorineural hearing loss (Neonatal Inhaled Nitric Oxide Study Group 1997).

Meta-analysis of 11 randomised trials demonstrated that the effect of iNO in preterm babies depends on the timing of administration and the population (Barrington and Finer 2007). Early rescue treatment based on oxygenation criteria did not affect mortality or BPD rates and there was a trend towards an increase in ICH. Early, routine use for intubated infants, however, was associated with a just significant reduction in the combined outcome of death or BPD (relative risk (RR) 0.91, 95% confidence interval (CI) 0.84–0.99) and a reduction in the incidences of severe ICH and PVL (RR 0.70, 95% CI 0.53–0.91). One study, however, was from a single centre (Schreiber et al. 2003) and in the other (Kinsella et al. 2006) the positive effects were only in infants with a birth-weight between 1000 and 1250 g. In a subsequent large trial ($n = 800$), in which preterm infants were randomised to early, prolonged, low-dose iNO therapy, no significant differences were demonstrated in any important outcomes (Mercier et al. 2010). In the meta-analysis, overall use of iNO after 3 days based on an elevated risk of BPD showed no effect on BPD (Barrington and Finer 2007). In one trial (Ballard et al. 2006), however, the rate of survival without BPD at 36 weeks' postmaturational age was higher in the iNO group, who were also discharged home sooner and received supplementary oxygen for a shorter time (Ballard et al. 2006). At follow-up of that trial, the iNO-treated infants received significantly less bronchodilators, inhaled and systemic steroids, diuretics and supplemental oxygen after discharge, but there were no significant differences in the rates of rehospitalisation or wheezing (Hibbs et al. 2008).

iNO delivery. Studies in term infants have demonstrated that levels of 5 ppm may be equally as effective as higher doses (Davidson et al. 1998; Wood et al. 1999), but lower doses (2 ppm) are not (Cornfield et al. 1999). Indeed, initial treatment with a subtherapeutic dose of iNO may diminish the clinical response to higher doses and have adverse sequelae (Cornfield et al. 1999). It has been recommended to start at 20 ppm in term newborns with PPHN; increasing to 40 ppm does not generally improve oxygenation in infants who have failed to respond to 20 ppm (Kinsella 2008). iNO can be delivered during transport; the method of delivery is influenced by the mode of transport either by road or by air (Lutman and Petros 2008).

NO has a very short duration of action; thus, rebound vasoconstriction and hypoxaemia can result if the NO is suddenly withdrawn. Therefore, to prevent sudden withdrawal of NO during routine nursing procedures, in-line suction devices are recommended to prevent interrupting the circuit and handbagging circuits should contain an additional iNO source. It is important to wean iNO as soon as oxygenation has improved and the baby has stabilised, otherwise tolerance may occur. During weaning from iNO, the level should be gradually reduced; decreasing to 1 ppm minimises the deterioration in oxygenation (Davidson et al. 1999). Increasing the inspired oxygen concentration by 10–20% immediately prior to cessation of iNO may also be helpful. Scavenging is not necessary in a well-ventilated environment (8–12 air changes per hour) but, even so, environmental checks are recommended to reassure staff that accidental macrocontamination has not occurred. See above: it is essential to exclude congenital heart disease in neonates being considered for iNO.

Infants at or near term with hypoxic respiratory failure (an oxygenation index of at least 25) should be considered for iNO, but only after their lung volume has been optimised and their cardiovascular status stabilised. Neonates who are hypoxaemic secondary to congenital heart disease, right ventricular-dependent circulation, severe left ventricular dysfunction, duct-dependent circulation or methaemoglobinaemia should not be given iNO. There is currently insufficient evidence to recommend routine use of iNO in prematurely born babies or in term babies with CDH.

Side-effects. NO should be administered only if continuous NO and nitrogen dioxide (NO₂) monitoring are available and there is immediate access to methaemoglobin analysis (Young and Dyar 1996). NO reacts rapidly with O₂ to form NO₂, which is toxic to the lung. The nitrosylhaemoglobin produced by NO binding to haemoglobin is rapidly converted to methaemoglobin, which is then reduced by methaemoglobin reductase in erythrocytes. Unfortunately, immature infants and those of certain ethnic groups have low levels of methaemoglobin reductase. Particularly in VLBW babies with RDS (Mupanemunda and Edwards 1995), care needs to be taken that NO₂ is not being formed (Miller et al. 1994), and that the baby is not developing methaemoglobinaemia (Walsh-Sukys 1993; Kinsella and Abman 1995). These problems are more likely if high concentrations of NO (Ahluwalia et al. 1994) are used for prolonged periods in high inspired oxygen concentrations (Miller et al. 1994). Inhaled NO administration has been associated with an increased bleeding time (George et al. 1998). It seems prudent to try to avoid iNO therapy in babies with a low platelet count or a bleeding diathesis, until these have been treated.

Phosphodiesterase inhibitors

Phosphodiesterases (PDEs) are enzymes which catalyse the hydrolytic cleavage of the 3' PDE bond of the cyclic nucleotides (cGMP and AMP), which play a central role in pulmonary vascular smooth-muscle relaxation. PDE inhibitors which have been used to treat neonates with pulmonary hypertension include dipyridamole (a non-specific PDE₅ inhibitor), milrinone (a PDE₃ inhibitor) and sildenafil (a PDE₅ inhibitor). Milrinone administration has been associated with improvement in oxygenation in neonates unresponsive to iNO (Bassler et al. 2006; McNamara et al. 2006), but some of the infants developed severe ICH (Bassler et al. 2006). In animal models of pulmonary hypertension, sildenafil (a PDE₅ inhibitor) was more effective than iNO in the treatment of pulmonary hypertension (Shekerdemian et al. 2002). Sildenafil has been shown selectively to reduce pulmonary vascular resistance in both animal models and humans. It produces vasodilation by increasing

cGMP by inhibiting the PDE involved in degradation of cGMP to guanosine monophosphate (McNamara et al. 2006). In a small trial, infants with oxygen index (OI) >25 were randomised to receive oral sildenafil (1 mg/kg 6-hourly) or placebo; the infants who received sildenafil experienced an improvement in oxygenation. Six of seven sildenafil-treated infants survived compared with only one of the six controls (McNamara et al. 2006). Despite the limited evidence available, sildenafil is being increasingly used (Hunter et al. 2009). Sildenafil has been used to support infants as they are being weaned off iNO (Konig 2009).

Calcium channel antagonists

Diltiazem has reduced right ventricular pressure in neonates with PPHN (Islam et al. 1999).

Endothelin receptor antagonists

Bosentan is an orally active dual endothelin receptor antagonist (ETA and ETB) and has been shown to reduce PVR and pulmonary arterial pressure in pulmonary hypertension in adults. Successful use in infants is limited to a few case reports (Nakwan et al. 2009).

Inhaled ethyl nitrite gas

Inhaled O-nitrosoethanol gas administered to seven babies with PPHN produced sustained improvements in oxygenation, without adverse effects (Moya et al. 2002).

Monitoring babies with persistent pulmonary hypertension of the newborn

This has to be meticulous and continuous. An indwelling continuously recording Pao₂ cannula should be placed in the aorta, but the umbilical artery Pao₂ measurements should be supplemented by a measure of the preductal Pao₂, using either a right radial artery catheter or a transcutaneous monitor placed on the right upper chest. Preductal (right hand) and postductal (either foot) Spo₂ measurements give useful additional information.

Weaning the baby with persistent pulmonary hypertension of the newborn off therapy

Once the baby has acceptable blood gases weaning can begin. This should be done cautiously as, for some days afterwards, a fall in PAP and a decrease in the right-to-left shunt can result in the pulmonary arteries once more going into spasm, perhaps due to the sensitising effects of alkalaemia (Gordon et al. 1993). The ventilator pressure should be reduced to <30 cmH₂O first, and then the rate of infusion of the vasodilator drugs reduced. In PPHN, the ventilator pressures should never be reduced by more than 1–2 cmH₂O increments and the oxygen concentration by no more than 3–5% increments.

Complications

If a pneumothorax occurs, it must be drained; the hypoxaemia caused by a pneumothorax may so aggravate the pulmonary arterial vasoconstriction that it pushes the baby into irreversible hypoxaemia, hypotension and bradycardia. PIE is particularly difficult to manage, as a reduction in ventilator pressure will almost inevitably result in a rise in Paco₂ and a reduction in pH and Pao₂, with worsening of the PPHN. The preterm baby with PPHN who is severely hypoxaemic, acidotic and/or hypotensive is at risk of brain injury, particularly if hypocapnia is used as treatment.

Natural history and prognosis

This varies with the aetiology. Many neonates respond promptly to treatment and the resulting mortality is low, in the 10–20% range, with most of the deaths being due to complications of prematurity or the neurological sequelae of severe birth asphyxia. For those requiring ECMO with primary PPHN or PPHN complicating RDS or MAS, survival figures of 80–90% are reported (p. 525). Most babies die either from irreversible hypoxia secondary to the PPHN or from myocardial failure as bacterial toxins cause arrhythmias or profound hypotension. The results in diaphragmatic hernia are given in Chapter 27, part 6.

Sequelae

Whether or not sequelae occur in survivors depends on whether the intensity of respiratory support caused BPD and whether any neurological damage resulted from severe hypoxia.

Meconium aspiration syndrome

MAS results from the inhalation of meconium before, during or immediately after delivery.

Incidence

In Europe the incidence is between 1:1000 and 1:5000, whereas in North America rates of 2–5:1000 have been reported. In Australia and New Zealand, the rate of MAS was 0.43:1000, with a decrease in incidence between 1995 and 2002 (Dargaville and Copnell 2006). Five per cent of babies born through meconium-stained liquor develop MAS (Cleary and Wiswell 1998).

Aetiology

Meconium inhalation

To develop MAS, an infant must pass meconium, inhale it and the inhaled material must damage the lungs. All these factors are inextricably interlinked with the presence of fetal asphyxia.

Passage of meconium

An overall prevalence of 8–22% for the presence of meconium in liquor is quoted (Gregory et al. 1974; Ramin et al. 1996; Cleary and Wiswell 1998). Meconium aspiration is a disease of term or postterm babies (Ch. 12). Meconium staining of the liquor occurs in 5% or less of preterm pregnancies (Mazor et al. 1995), when it suggests chorioamnionitis, but the prevalence increases to 10% or more after 38 weeks, reaching 22% in patients at a gestational age of 42 weeks, and 44% in babies who deliver 1–2 weeks later.

The fetal passage of meconium may be due to a vagal reflex, but more convincing are the data showing that motilin, which is produced mainly by the jejunum and stimulates peristalsis, is very low in preterm infants and non-asphyxiated term infants, but is raised in asphyxiated term babies who pass meconium intrapartum (Mahmoud et al. 1988).

Inhalation of meconium

Meconium inhalation can occur before the onset of labour, as meconium has been found in the lungs of stillborn babies (Brown and Gleicher 1981) and in babies who die in the early neonatal

period, who could not have inhaled meconium intrapartum (Manning et al. 1978; Byrne and Gau 1987; Sunoo et al. 1989). Prolonged severe fetal hypoxia can stimulate fetal breathing, to the extent that amniotic fluid is inhaled (Hooper and Harding 1990), and fetal gasping movements also draw intra-amniotic material into the alveoli (Boddy and Dawes 1975; Manning et al. 1979). Perinatally, meconium inhalation can occur if the baby breathes or gasps with the mouth, pharynx or larynx full of meconium-stained liquor. This may occur late in the second stage of labour, particularly if there is a severe mixed acidaemia with a fetal pH <7.0 (Ramin et al. 1996), when the raised P_{aCO_2} may have provoked intrapartum gasping. Postnatally, any meconium in the upper airway potentially can cause MAS. If meconium is inhaled, development of severe MAS depends in part on whether there is coexisting asphyxia (Katz and Bowes 1992; Hernandez et al. 1993).

Effect of meconium on the lungs

Meconium is a sticky material composed of inspissated fetal intestinal secretions. When inhaled, it probably has at least four interacting deleterious effects on a neonatal lung (Fig. 27.34):

1. It creates a ball valve mechanism in the airways whereby air can be sucked in past the plug but cannot be exhaled. This increases airways resistance, mainly in expiration, causing gas trapping, lung overdistension and pneumothorax.
2. It acts as a chemical irritant. Inflammatory cells and mediators are released, which affect vessel contractility, lead to capillary leakage and injure the lung parenchyma. The cytokines cause airway and alveolar epithelial necrosis (Zagariya et al. 2000). Cell injury and apoptosis may also result from the high concentrations of phospholipase A_2 found in meconium (Holopainen et al. 1999). Thus, 24–48 hours after inhalation there is an exudative and inflammatory pneumonitis with alveolar collapse and cellular necrosis.
3. The organic nature of inhaled material, although initially sterile, may predispose the baby to pulmonary infection, particularly with *Escherichia coli*. Meconium may inhibit phagocytosis and the neutrophil oxidative burst (Clark and Duff 1995), hence bacteria can grow in meconium-stained amniotic fluid. Meconium staining of the liquor may be a marker of chorioamnionitis, predisposing the baby to congenital pneumonia (Wen et al. 1993; Mazor et al. 1995) and meconium inhibits polymorph function (Clark and Duff 1995).
4. Meconium inhibits surfactant function and production (Clark et al. 1987; Moses et al. 1991; Dargaville et al. 2001); the inhibition is in a concentration-dependent manner (Sun et al. 1993). The water/methanol-soluble phase (bilirubin and proteins) and, particularly, the chloroform-soluble phase (free fatty acids, triglycerides and cholesterol) of meconium inhibit surfactant (Sun et al. 1993). In addition, phospholipase A_2 degrades surfactant (Schiff et al. 1993) and lysophosphatidylcholine can inhibit surfactant secretion (Grossman et al. 1999). Meconium alters the morphological ultrastructure of surfactant and hence decreases its surface tension-lowering ability (Bae et al. 1998). Infants with severe MAS, i.e. requiring ECMO, have been shown to have lower levels of phosphatidylcholine (Janssen et al. 2006).

These four factors combine to cause the severe airway and alveolar disease which is more likely to occur if there is coexisting asphyxial lung damage (Jovanovic and Nguyen 1989; Katz and Bowes 1992; Ramin et al. 1996).

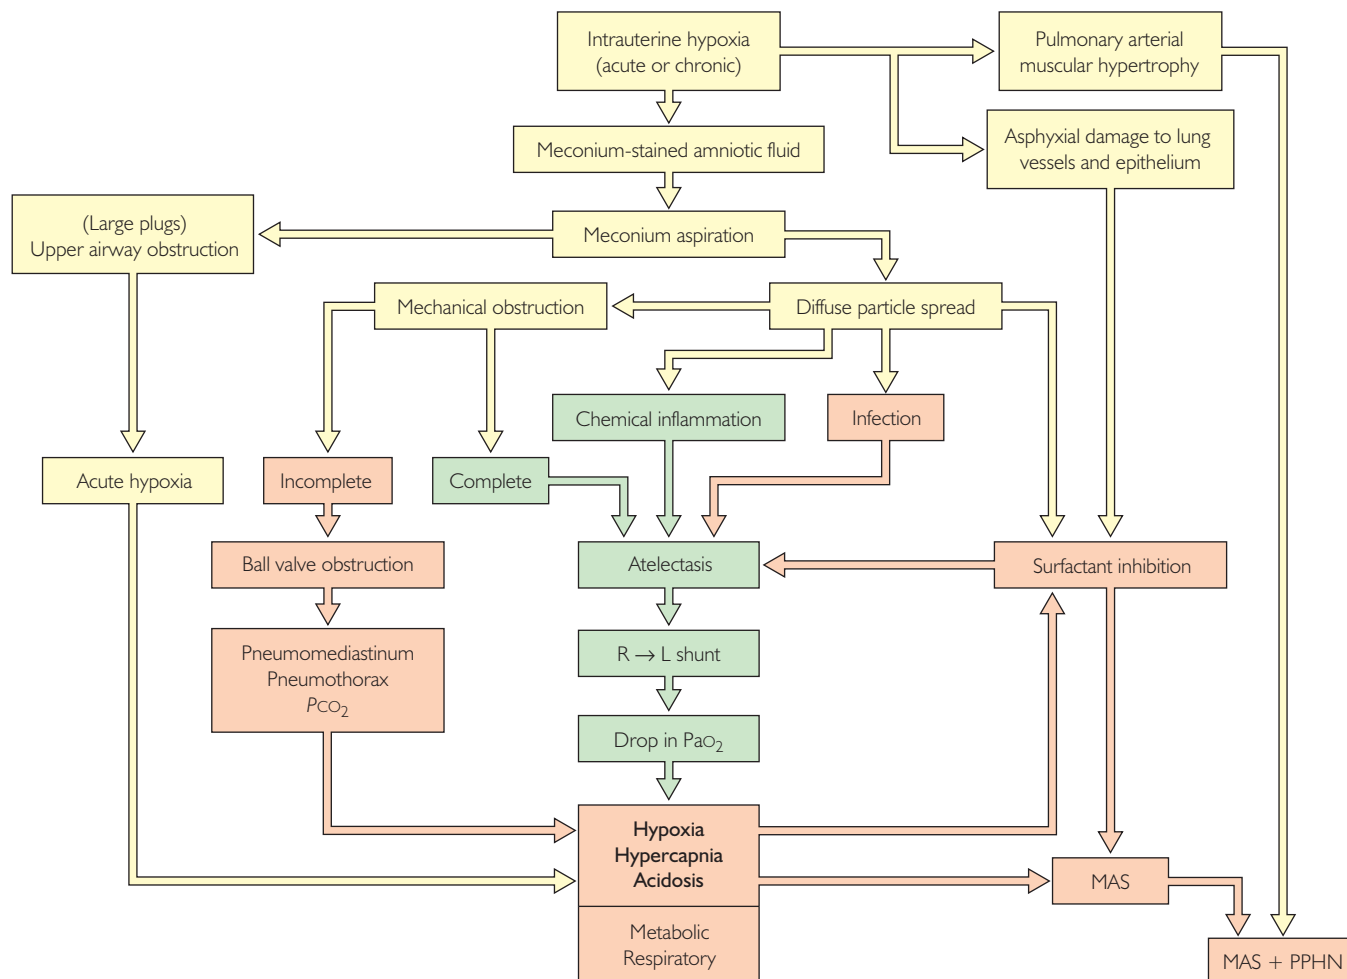

Fig. 27.34 Aetiology of meconium aspiration syndrome (MAS) and its associated clinical syndromes. PPHN, persistent pulmonary hypertension of the newborn.

Effect on pulmonary vasculature

A rise in PAP occurs in all babies with hypoxia and acidaemia (p. 455). Meconium in the lung increases PAP, even if the blood gases are normal (Tyler et al. 1978). The inflammatory response (see above) results in release of vasoactive substances, which cause vasoconstriction; in addition, there may be maldevelopment of the pulmonary vessels secondary to chronic hypoxia (p. 450).

Pathology

Petechial haemorrhages may be present on the lung surfaces due to acute hypoxaemia, particularly if death has occurred rapidly after birth. The lungs may be greenish yellow in colour and the cut surface can show congestion and haemorrhage and meconium can be expressed from the cut ends of the smaller bronchi. The pathognomonic histological feature is the presence of amniotic squames, together with meconium in the terminal airways. Meconium itself appears as a granular eosinophilic material, often containing small yellow meconium bodies. Aspirated material will stimulate a macrophage reaction, but, in the absence of an infective process, acute inflammation with neutrophils is not a feature. In addition to the meconium, hyaline membranes are frequently present. There may also be non-specific changes of an asphyxial insult to the lung,

which include interstitial oedema and haemorrhage. The changes of PPHN may be seen in the pulmonary vascular tree. Infants who die of MAS will have been ventilated at high pressures and thus the histological changes merge into those of BPD. In babies with MAS who die early in the neonatal period, severe asphyxial damage may be seen in other organs, in particular the brain, kidney and myocardium.

Prevention

Antenatal

Attempts to prevent MAS have largely proved unsuccessful. In a large randomised trial (Fraser et al. 2005) which included 1998 pregnant women in labour at 36 weeks or more of gestation who had thick meconium staining of the amniotic fluid, those randomised to amnioinfusion did not have a reduced risk of moderate or severe MAS, perinatal death or other major maternal or neonatal disorders. Suppression of fetal breathing movements by maternal narcotic administration, although successful in a baboon model (Block et al. 1981), did not reduce the incidence of MAS in two clinical series (Dooley et al. 1985; Byrne and Gau 1987).

Intrapartum/postpartum

Timing and mode of delivery

A prospective study (Yoder et al. 2002) demonstrated that reduction in postterm delivery was the most important factor in decreasing the incidence of MAS. MAS is frequently reported to be higher in infants born by caesarean section rather than vaginal delivery; caesarean sections are usually performed on infants with fetal distress, a risk factor for MAS, which may explain the association.

Airway suctioning

Although it is clear that some meconium can be inhaled prelabour, it is assumed that many cases of MAS arise due to inhalation of meconium during the few minutes before birth. In uncontrolled studies, meticulous clearing of the airway at delivery was reported to reduce the incidence of MAS (Gregory et al. 1974; Ting and Brady 1975; Carson et al. 1976). The results of several subsequent studies, however, suggested that routine suctioning through the cords or intubation with endotracheal toilet was not justified, as the manoeuvres not only failed to reduce the incidence of MAS but also were associated with increased morbidity (Falciglia 1988; Linder et al. 1988; Falciglia et al. 1992). Randomised trials have now been reported which have addressed whether intrapartum intubation and tracheal suctioning are necessary. No significant differences in the incidence of MAS or in other major outcomes were demonstrated between babies randomised to receive either naso- or oropharyngeal suctioning prior to delivery of the shoulders or no suctioning (Vain et al. 2002). Similarly, no significant differences were demonstrated in the incidence of MAS or other respiratory complications between apparently vigorous infants who were randomised to intubation and tracheal suctioning or routine delivery room care (Wiswell et al. 2000). In addition, meta-analysis of the results of four randomised trials which included vigorous term meconium-stained babies (Halliday 2000) did not demonstrate significant benefit with regard to mortality, MAS or hypoxic–ischaemic encephalopathy (HIE) from routine endotracheal intubation at birth as compared with routine resuscitation, including oropharyngeal suction. The event rates for the outcomes, however, were low, thus making reliable estimates of treatment effect impossible. Nevertheless, on the evidence to date, intubation and suctioning should be restricted to newborns who are depressed (Bhutani 2008) – that is, they have a heart rate of less than 100 beats/min, poor respiratory effort and poor tone. As soon as possible after delivery, affected babies should be handed to the paediatrician, who should gently insert a laryngoscope and carefully clear the upper airway of any meconium-stained material. If no meconium is seen below the cords, it is not worth proceeding (Linder et al. 1988). If, however, meconium is seen, direct tracheal suction is indicated. Studies in animal models have demonstrated that inhaled meconium stayed in the trachea and major bronchial divisions for several minutes after the onset of respiration and was, therefore, still in a site from which it could be aspirated (Pfenninger et al. 1984).

IPPV

The indications for resuscitation by IPPV (Ch. 13.1) are not affected by the presence of meconium, other than it is always important to clear as much meconium from the airway as possible before applying positive-pressure ventilation.

Compression of the neonatal thorax

This is no longer recommended, as it seems unlikely to prevent gasping, which has a large diaphragmatic component, and compression of the thorax can stimulate respiratory efforts.

Bronchial lavage

Instilling water or saline into the lower respiratory tract is controversial; an increase in wet lung has been noted following this procedure (Carson et al. 1976) and repeated bronchial lavage can do harm. Once on IPPV, tracheal suction with saline lavage, however, resulted in a 35% improvement in airway resistance in one study (Beeram and Dhanireddy 1992). Surfactant lavage can be beneficial (see below).

Postnatal gastric aspiration

Many clinicians routinely aspirate the stomach of a baby who has inhaled meconium at delivery, assuming the baby will have also swallowed meconium and gastric aspiration will prevent subsequent meconium inhalation following vomiting or reflux. Routine gastric lavage prior to feeding, however, did not decrease the incidence of MAS in babies born through meconium-stained liquor (Narchi and Kulaylat 1999).

Clinical signs

The baby is usually mature, or postmature, with long fingernails and a dry skin which soon starts to flake. The skin, nails and umbilical cord are often stained greenish yellow. The baby is not usually febrile, unless secondarily infected. Peripheral oedema is not a feature, and, if present, suggests either renal damage or iatrogenic fluid overload.

Respiratory

The baby has tachypnoea, which may exceed 120/min. Intercostal and subcostal recession occurs and there is use of accessory muscles and flaring of the nostrils. An expiratory grunt may be heard. The meconium in the airways causes widespread sticky crepitations and occasional rhonchi, air trapping and an overdistended chest with an increased anteroposterior diameter. The baby may remain symptomatic for only 24 hours or be very dyspnoeic for 7–10 days before recovery. In patients who required ventilation, the respiratory disease has usually abated to a resting tachypnoea of 50–70/min in room air by 14 days of age.

Cardiovascular

In the absence of asphyxial damage to the myocardium, there are no specific cardiovascular features of MAS. Hypotension suggests myocardial damage, as do signs of congestive heart failure. In uncomplicated MAS, the heart rate tends to be around 110–125/min, and the BP is maintained within the normal range. If PPHN (pp. 495–504) develops, S2 may remain single, and there may be the murmur of tricuspid incompetence (Ch. 28).

Abdominal examination

The liver and spleen are often palpable because of downward displacement of the diaphragm caused by air trapping. In a severely affected infant, bowel sounds may be absent, with delayed passage of meconium. There may be urinary retention and bladder distension in babies with severe neurological problems or those who receive pancuronium.

Central nervous system

Depending on the severity of the coexisting neurological insult, the baby may behave normally or show features of HIE (Ch. 40.4).

Differential diagnosis

Apparently faeculent liquor may be due to yellow-green bilious vomiting secondary to upper gastrointestinal tract obstruction (Wynn and Schreiner 1979). It is important to exclude concurrent illness, especially infection and PPHN.

Pathophysiology

The respiratory failure and hypoxaemia in babies with MAS are due to stiff lungs, marked ventilation–perfusion imbalance and pulmonary hypertension precipitating extrapulmonary right-to-left shunts. Babies with MAS have a reduced compliance and tidal volume and an increased airways resistance, but the tachypnoea increases the minute volume to twice normal (Bancalari and Berlin 1978). In the early stages of the disease, when the airways are plugged by meconium, there is a marked ventilation–perfusion abnormality, which lessens as the lungs recover. In those who develop PPHN, the PAP will be higher than the systemic, with right-to-left shunting through the ductus arteriosus and/or the foramen ovale.

Investigations

Haematological

The nucleated red blood cell (Dollberg et al. 2001) and the white cell (Manroe et al. 1979; Merlob et al. 1980) counts are often raised. White cell function is reduced (Clark and Duff 1995). Thrombocytopenia often occurs in neonates with meconium aspiration who have PPHN (Segal et al. 1980), are ventilated (Ballin et al. 1987) or develop DIC secondary to severe asphyxia (Ch. 30).

Biochemical

If coexisting asphyxia is severe, there may be inappropriate ADH production and hyponatraemia (Ch. 35.2). Renal failure secondary to acute tubular necrosis may cause hyperkalaemia and a raised urea. Hypocalcaemia may also occur, as in any critically ill neonate (Ch. 34.2).

Blood gases

Hypoxia is common, but in mature infants with mild to moderate disease and an efficient respiratory pump, ventilation is not a problem and the P_{aCO_2} may even be low, normal or only slightly raised. A $P_{aCO_2} > 8$ kPa (60 mmHg) is unusual and is seen only in patients with severe lung disease who eventually need ventilation.

Changes in pH initially reflect the metabolic acidemia of intrapartum asphyxia; mature babies commonly correct their acidemia spontaneously from pH levels in the 7.10–7.15 range and base deficit values of 10–15 mmol/l (Spencer et al. 1993). After the first hour or two, persisting metabolic acidemia indicates an underlying problem such as sepsis, hypotension and/or renal failure, which should be sought and remedied.

Urine analysis

Many babies with MAS, although not in overt renal failure, have a raised urinary β_2 -microglobulin, indicating they have incurred some renal damage (Cole et al. 1985). The urine may be greenish-brown in colour as a result of the absorption of meconium pigments across the pulmonary epithelium and their excretion in the urine (Dehan et al. 1978).

Echocardiography

In uncomplicated MAS, the ECG and echocardiogram will be normal. If there has been severe intrapartum asphyxia, there may be ECG changes suggesting subendocardial ischaemia, and the echocardiogram will show reduced cardiac contractility. In those with PPHN, echocardiography demonstrates right-to-left shunting at ductal and atrial levels and a jet of tricuspid insufficiency, indicating raised right ventricular pressures.

Chest X-ray

The common early changes are widespread patchy infiltration and, in 20–30% of patients, small pleural effusions. Overexpansion is also common in the early stage. In mild to moderate cases, the changes resolve within 48 hours. In severe cases, as the disease progresses, by 72 hours of age with or without ventilation the appearance is often changed to that of diffuse and homogeneous opacification of both lung fields, as a result of a pneumonitis and interstitial oedema secondary to the irritant effect of the inhaled meconium (Fig. 27.35). These changes gradually resolve over the next week, but in severe cases the X-ray may still be abnormal at 14 days, and may merge into the pattern seen in BPD, although this is uncommon. Airleaks, in particular pneumothorax and pneumomediastinum, are very common in MAS (p. 486).

Microbiology

All babies suffering from MAS should have an infection screen as soon as possible after admission to the NICU.

Monitoring

There is a temptation to undermonitor full-term babies with MAS because, despite marked tachypnoea and a very abnormal CXR appearance, they often look surprisingly pink and vigorous. This temptation should be resisted, not only because of the importance of early detection of blood gas abnormalities, electrolyte disturbance or hypotension before secondary effects develop, but also because the baby with MAS has a major risk of sudden deterioration due to a tension pneumothorax.

Fig. 27.35 Severe confluent pneumonitis in meconium aspiration syndrome.

Treatment

The aim is to support the baby until alveolar macrophages clear the debris and lung function returns to normal.

Oxygen therapy

Many babies with MAS can be managed by giving an appropriate concentration, up to 80–90%, of warmed humidified oxygen. The oxygen saturation should be maintained at 95% or the P_{aO_2} greater than 10 kPa during the acute stage of the illness. In many mild cases, oxygen therapy at 40% or less for 24–48 hours is all that is required and P_{aO_2} in room air is normal by 48 hours of age.

Acid–base homeostasis

Carbon dioxide retention is only a problem in severe cases. A P_{aCO_2} of 7.5–8 kPa (55–60 mmHg) is acceptable, providing the pH is sustained above 7.25. Intubation and ventilation are indicated if the P_{aCO_2} rises above 8 kPa (60 mmHg), particularly in the presence of a $P_{aO_2} < 6$ kPa (45 mmHg) early in the disease.

The first blood gas analysis taken after birth may show a marked metabolic acidemia. Provided that the baby is otherwise stable, with a normal P_{aO_2} and P_{aCO_2} , and is passing urine, base deficits of 10–15 can be left to correct spontaneously (Ch. 35.2). The acidemia should be corrected, however, if the base deficit is greater than 15 or the pH below 7.10.

In babies who show features of HIE, more rigid control of the blood gases is required (Ch. 40.4); hypoxia, hypercapnia and acidemia are all undesirable. This indication for intubation and ventilation takes priority over the more conservative management of the blood gases outlined for babies with uncomplicated lung disease.

Continuous positive airways pressure

CPAP can improve oxygenation, but is likely to increase the risk of pneumothorax. In addition, use of nasal prongs in term neonates usually makes them irritable and restless, with a fall in P_{aO_2} .

Intermittent positive-pressure ventilation

Babies with MAS can be very difficult to ventilate; a long expiratory time and a low level of PEEP are theoretically best in MAS; elevation of PEEP can improve oxygenation, but increases the risk of pneumothorax. Administration of a neuromuscular blocking agent is virtually always required. When the blood gases start to improve, weaning can usually be rapid. Once the infant is in <50–60% oxygen and has peak pressures of 20 cmH₂O, neuromuscular blockade can be stopped. We then prefer to transfer infants to PTV and wean by a reduction in peak pressures, extubating infants into headbox oxygen without a period on CPAP.

High-frequency ventilation

HFJV used with surfactant, but not alone, has been reported to improve oxygenation in MAS (Davis et al. 1992). A retrospective review, however, reported no significant difference in the outcome of infants with MAS supported by HFJV (Baumgart et al. 1992). HFOV, particularly when used with NO, improved oxygenation and outcome in infants with PPHN and MAS (Kinsella et al. 1997).

Extracorporeal membrane oxygenation

In a randomised trial, ECMO improved survival of MAS infants with an oxygenation index >40 by 50% (UK Collaborative ECMO Trial

Group 1996). Approximately 94% of babies with MAS who are managed with ECMO survive; this does not appear to be at an increased risk of disability or adverse neurological outcome (UK Collaborative ECMO Trial Group 1998).

Pulmonary vasodilators (p. 498)

Drugs used to treat pulmonary hypertension can be effective in babies with MAS (Goetzman et al. 1976; Stevenson et al. 1979; Kinsella et al. 1992; Finer et al. 1994; Tolsa et al. 1995). Inhaled NO improves oxygenation and decreases the need for ECMO (Neonatal Inhaled Nitric Oxide Study Group 1997; Clark et al. 2000) but in these trials no other significant differences in major outcomes were noted.

Surfactant

Exogenous surfactant therapy has been used with anecdotal success (Auten et al. 1991; Khammash et al. 1993). In a randomised prospective study, babies who received surfactant within 6 hours of birth had fewer airleaks, were on IPPV and oxygen for a shorter period and were much less likely to require ECMO (Findlay et al. 1996). The maximum effect on oxygenation was after three doses or more, suggesting that larger doses are required in MAS. Once on ECMO, the use of surfactant speeds recovery and the rate of weaning from ECMO (Lotze et al. 1993). In a randomised trial, up to four doses of surfactant reduced the need for ECMO in term infants with respiratory failure, half of whom had MAS (Lotze et al. 1998); however, there were no other significant differences in outcome. Meta-analysis of the results of four randomised trials demonstrated that surfactant administration reduced the risk of requiring ECMO, but not mortality (El Shahed et al. 2007).

Lavage with surfactant may be a particularly effective method of improving gas exchange by washing out meconium and the products of inflammation (Ohama et al. 1994), as well as diluting the meconium. Multiple small-volume dilute surfactant lavages have been reported to improve oxygenation (Lam and Yeung 1999). Large aliquots (15 ml/kg) have also been used without adverse acute effects and a trend to improvement in oxygenation at 48 hours compared with controls (Dargaville et al. 2007). In a randomised trial, no advantages of lavage compared with bolus were found with regard to length of hospitalisation or complications, but the sample size was small and the lavage group had improvements in oxygenation, decreases in MAP and A–a gradients (Gadzinowski et al. 2008). In a randomised trial, lavage with the protein-containing synthetic surfactant Surfaxin (KL-4 surfactant) improved lung function (Wiswell et al. 2002).

Antibiotics

The presence of organic and potentially infected material in the liquor and in the lung may predispose to pneumonia. Neonates with MAS should be put on broad-spectrum antibiotics, penicillin and gentamicin. The antibiotics should be discontinued when the culture results are known to be negative or after 7 days, when the baby is in the convalescent stage of the illness and requiring less than 30–40% oxygen.

Blood volume and blood pressure

If the haemoglobin falls below 13 g/dl or the PCV below 40%, the baby should be transfused. BP control is essential in all neonates with MAS, aiming to keep the pressure within the normal range (Appendix 4). Hypotension is usually only a problem in babies

who have suffered severe intrapartum asphyxia with coexisting myocardial injury or after vasodilators. If hypotension occurs, it is managed in the usual way with volume expansion and/or inotropes, depending on the neonate's myocardial and renal function (Ch. 35.2).

Physiotherapy

In neonates with mild to moderate disease who are not ventilated and require less than 60% inspired oxygen concentration, chest physiotherapy is rarely necessary. In the severely affected baby who is intubated and paralysed, chest percussion and ETT suction may be helpful, but should be continued only as long as this produces significant amounts of greenish material and abandoned if the neonate becomes hypoxaemic.

Steroids

In an animal model, although steroids reduced respiratory symptoms due to MAS, the mortality rate was higher (Fox and Duara 1983). In a randomised trial involving 35 infants (Yeh et al. 1977), steroid treatment in the first 6 hours after birth resulted in no significant differences in the duration of ventilation or survival and the steroid-treated group experienced an increased time to wean. In a subsequent small trial (Wu et al. 1999), major outcomes (mortality and BPD) were not influenced by steroid therapy. More recently, steroid administration resulted in more rapid improvement in ventilated infants with MAS and PPHN (Da Costa et al. 2001). Further studies are required to determine if steroid administration influences long-term outcomes.

Complications

Babies with MAS may suffer from HIE (Ch. 40.4) and renal failure (Ch. 35.2), which are dealt with elsewhere.

Pneumothorax, airleaks

Pneumothorax, pneumomediastinum, pneumopericardium and pneumoperitoneum can all occur; approximately 50% of ventilated MAS babies suffer some form of airleak, but PIE is unusual.

Persistent pulmonary hypertension

This is a common complication of severe MAS, and appears to be particularly frequent in fatal cases (Wiswell et al. 1990).

Bronchopulmonary dysplasia

This is a rare complication of MAS, although it may occur in any baby who survives after long-term high-pressure IPPV.

Mortality

Mortality rates are between 4% and 12% (Cleary and Wiswell 1998). The majority of deaths are from respiratory failure, PPHN or airleaks (Wiswell et al. 1990), but some die from the associated neurological or renal sequelae of severe asphyxia.

Morbidity

Neurological

The neurological sequelae in these babies are those of the coexisting HIE (Ch. 40.4).

Pulmonary

MAS predisposes to long-term respiratory morbidity (MacFarlane and Heaf 1988; Swaminathan et al. 1989; Yuksel et al. 1993a). In a single-centre study (Beligere and Rao 2008), infants with MAS had later neurodevelopmental delay, even if they responded to conventional treatment. At school age, although the majority of neonates who survived MAS were completely asymptomatic, 30–40% had problems with asthma and less than half had completely normal lung function tests (MacFarlane and Heaf 1988; Swaminathan et al. 1989). Other data (Koumbourlis et al. 1995) also suggest that meconium aspiration predisposes to increased bronchial hyperreactivity. The lung function abnormalities at follow-up relate to the severity of MAS (Wilcox et al. 1994). At 6–9 years of age, evidence of residual airways disease was seen in patients who had moderate to severe MAS (Cordier et al. 1984), whereas 12 children who had had mild MAS had normal lung function (Stevens et al. 1988).

Aspiration of amniotic fluid

Postmortem studies of stillbirths have revealed that amniotic squames can be inhaled by the fetus in utero, presumably as a result of 'terminal' gasping activity preceding intrauterine death (Wigglesworth 1984). The importance of less severe manifestations of this entity, in the absence of meconium staining of the amniotic fluid, is speculative, but there is a postnatal lung disease attributed to the inhalation of non-meconium-stained amniotic squames (Schaffer and Avery 1977).

Aspiration of fluid at delivery

Aspiration of blood can result in early-onset respiratory distress and a radiographic appearance of aspiration syndrome (Gordon et al. 2003). It occurs during birth by caesarean section or a vaginal birth complicated by abruptio placentae. Aspiration of 'pool' fluid during a water birth may also cause respiratory distress (Fig. 27.36).

Fig. 27.36 Bilateral changes due to aspiration of pool fluid at an underwater birth.

Table 27.8 Types of aspiration syndrome in the newborn

1. Sucking/swallowing incoordination
 - a. Prematurity
 - b. Secondary to structural malformation or neurological disorders:
 - Cleft palate, Pierre Robin syndrome
 - Tracheo-oesophageal fistula, laryngeal cleft
 - Hypoxic-ischaemic encephalopathy
 - c. Syndromes with poor sucking, e.g. Prader-Willi
2. Syndromes attributed to gastro-oesophageal reflux
 - a. In babies on intermittent positive-pressure ventilation – right upper lobe collapse
 - b. Wilson-Mikity syndrome
 - c. Apnoeic attacks
3. Massive regurgitation and inhalation of a feed

Other aspiration syndromes (Table 27.8)

In the neonatal period, aspiration can occur due to malfunction of coordination of sucking, swallowing and breathing.

Swallowing incoordination

Pathophysiology

The anatomical structure of the pharynx and larynx protects the airway from inhalation (Ch. 7.7) (Lund 1976) and there are defensive reflexes. The presence of any material in the pharynx initiates swallowing and reflex breath-holding (Wilson et al. 1981). If the airway remains threatened, additional reflexes, including more prolonged apnoea, choking, laryngospasm and coughing, are provoked (Pickens et al. 1988; Davies et al. 1989). These mechanisms provide a less effective shield over the airway in the neonatal period than they do in older children and adults. During sucking, the term neonate may have a reduction in ventilation (Al-Sayed et al. 1994), P_{aO_2} and heart rate (Mathew 1991), progressing in some infants to apnoea (Steinschneider et al. 1982; Guilleminault and Coons 1984; Mathew et al. 1985; Itani et al. 1988). This may be because of poor breathing/swallowing coordination or additional problems such as velopalatine insufficiency with reflux into the nasopharynx (Plexico and Loughlin 1981). The preterm neonate additionally has immature sucking/swallowing coordination (Shoemaker et al. 2007), which may be overwhelmed by oral feeding, and a high incidence of GOR (Newell et al. 1989a). If there has been brain damage, the neurological control of swallowing may be compromised. Preterm babies can protect their airway as well as those born at term, but these frequent challenges mean that its integrity may eventually be breached (Itani et al. 1988) and inhalation of stomach contents results. Even if the defence mechanisms are effective in preventing intrapulmonary inhalation, significant symptoms, especially apnoea (Newell et al. 1989a; Marino et al. 1995), may still result.

Coordinating sucking, swallowing and breathing becomes more difficult at all gestations if the neonate is sedated, for example by the transplacental passage of opiates, or if the neonate is tachypnoeic with RDS or TTN (Timms et al. 1993).

Other common causes of breathing/swallowing incoordination in both preterm and term babies are structural malformations in the upper airway or gastrointestinal tract, or neurological problems interfering with normal swallowing. Biochemical problems such as

hypoglycaemia or hyponatraemia may occasionally have the same effect. Most causes of dysphagia and sucking/swallowing incoordination are extremely rare and usually present with the primary disorder rather than with dysphagia.

Clinical features

The commonest manifestation of swallowing/breathing incoordination in the term baby is choking, spluttering and becoming transiently apnoeic and blue during a feed. The baby thereafter usually remains asymptomatic. Many of these babies are at the extreme end of the normal spectrum of the response to feeding (Mathew 1991). More serious examples are seen in babies who have brain damage or have abnormalities such as a cleft palate. In these, even saliva may continually collect in the pharynx and the baby will be 'mucousy'. In severe cases, babies have saliva dribbling from their mouths and may cough and splutter when trying to clear their airways: cyanosis and bradycardia can occur (Guilleminault and Coons 1984; Itani et al. 1988). Persisting retention of secretions in the pharynx and larynx, in addition to causing noisy breathing and upper respiratory tract symptoms, may result in tachypnoea and retraction, and, on auscultation, widespread conducted sounds are heard. Affected babies can have reflex apnoea caused by the presence of foreign materials in the larynx (Bartlett 1985).

Investigation and differential diagnosis

On the basis of the history and clinical examination, it should be possible to distinguish babies who have had a single or at most two or three episodes due to immature mechanisms being overwhelmed, from those with GOR or a chronic neurological or structural problem (Table 27.9). The clinical presentation of oesophageal atresia, with maternal polyhydramnios, followed by the baby having major problems with secretions in the first 2–3 hours, is sufficiently classical that it should not be missed. Other babies may have covert GOR, or may be refluxing into the nasopharynx during a feed, with subsequent reflex apnoea (Plexico and Loughlin 1981). Appropriate oesophageal pH (Newell et al. 1989a; Khalaf et al. 2001) or contrast studies will demonstrate the abnormality.

Treatment

If no clinical abnormality is found (which is usually the case) in a term baby who has been admitted to the neonatal unit following such an episode on the postnatal ward, breast- or bottle-feeding can be continued under careful supervision, proceeding to further investigation only if choking persists. In convalescent LBW neonates, or those with recognised neurological or structural problems, all that is usually necessary in the absence of signs of aspiration pneumonia is to omit one or two feeds, before carefully restarting them, by nasogastric tube if necessary.

Babies with a tracheo-oesophageal fistula or laryngeal cleft should have surgical repair as soon as possible (Ch. 29.4). Problems associated with palatal defects may be considerably improved by the use of a palatal prosthesis (Ch. 27.7). In babies with Pierre Robin syndrome, laryngomalacia or other surgical problems in which there is not only tongue/palate incoordination but also a structural predisposition to inhalation, and, in addition, no prospect of immediate surgical correction, the airways should be meticulously suctioned and the baby nursed prone. It may, however, occasionally be necessary to resort to tracheostomy in order to protect the lungs.

A small group of babies, typically those with severe neurological damage secondary to HIE or with a primary problem such as dystrophia myotonica, may have prolonged difficulties. Frequent

Table 27.9 Dysphagia in the newborn

Gross anatomical defects	
Palate	Cleft palate, submucous cleft
Tongue	Macroglossia, cysts, tumours, lymphangioma, ankyloglossia superior
Nose	Choanal atresia
Mandible	Micrognathia, Pierre Robin syndrome
Temporomandibular joint	Ankylosis (congenital or infective), hypoplasia
Pharynx	Cyst, diverticulum, tumour
Larynx	Cleft, cyst
Oesophagus	Atresia, stenosis, short oesophagus, web, diverticulum, duplication, lung buds, tracheo-oesophageal fistula
Thorax	Vascular rings
Neuromuscular incoordination	
Delayed maturation	Prematurity, normal variant
Cerebral palsy	All types
Brain damage	Postasphyxial, postinfection (prenatal or postnatal)
Abnormalities of the cranial nerve nuclei and their tracts	Bulbar and suprabulbar palsy
	Moebius syndrome
	Pharyngeal, cricopharyngeal incoordination (idiopathic, secondary to brain damage)
Congenital laryngeal stridor	
Myopathies	Myotonic dystrophy, myasthenia gravis
Hypotonia from any cause	Brain damage, Werdnig–Hoffman syndrome
Infections	Tetanus, polio, stomatitis, oesophagitis
Modified from Illingworth (1969).	

suctioning of the mouth and pharynx will be required and it may help to keep the baby lying prone or semiprone, allowing the baby's mouth to empty by gravity. Persistence of problems is an ominous prognostic feature; despite suctioning and positioning and meticulous nursing care, inhalation of secretions will eventually result, progressing to aspiration pneumonia, which is a common terminal event in such cases.

Gastro-oesophageal reflux (Ch. 29.3)

GOR should be suspected in neonates with apparently inexplicable and recurrent respiratory problems, especially if there is recurrent

apnoea unresponsive to theophylline (Newell et al. 1989a), a history suggesting reflux or recurrent vomiting, or right upper lobe collapse or consolidation on X-ray. The diagnosis should be confirmed by radiological or pH probe demonstration of reflux (Orenstein and Orenstein 1988; Newell et al. 1989a; Holopainen et al. 1999).

Treatment

If episodes of apnoea or recurrent pulmonary disease in a neonate are confirmed to be due to reflux, small frequent feeds or continuous milk infusion are advocated; nasojejunal feeds or thickened feeds may also be beneficial (Newell et al. 1989a). Antacids should be given if there is evidence of oesophagitis. Cisapride is no longer prescribed, because of the reports of toxicity and apparent lack of efficacy. Consequently, if the above measures fail, some clinicians prescribe another prokinetic agent, domperidone. Whether neonates benefit from any form of medical therapy for reflux has been questioned (Hrabovsky and Mullett 1986) and fundoplication may be necessary if problems from GOR persist. In our experience, this is rarely necessary, except in babies with chronic severe reflux and BPD.

Aspiration pneumonia

This may occur following one of the episodes of sucking/swallowing incoordination or reflux described above and is most likely to occur in babies with neurological defects or structural malformations. It may be covert due to reflux, or can follow an episode of massive regurgitation and vomiting, which usually only occurs in ill and convalescent babies of all gestations on the NICU. The baby, often still tube-fed, is found covered in vomit, and is usually cyanosed, apnoeic or gasping, and bradycardic.

Prevention

Most cases of aspiration pneumonia can and should be prevented by prompt clinical recognition and appropriate management of the disorders in which they are likely to occur (Table 27.8) and by careful attention to the feeding technique. Professional speech and language therapy input is essential for safe oral feeding in many of these babies.

Pathophysiology

The foreign material aspirated into the airway can have three effects: physical obstruction, chemical irritation and promotion of infection. All fluids, including water, are damaging, but gastric contents are particularly damaging because of their acidic pH (James et al. 1984). In the first few days after birth, the pH of a neonate's stomach contents can be 2.5 or less if the infant is unfed (Avery et al. 1966b) or fed only clear fluids with no buffering capacity. Inhaled curd is particulate and can obstruct airways, leading to lung collapse and/or consolidation, and may predispose to infection.

Clinical findings

In babies with sucking/swallowing incoordination, the features of their primary diagnosis will be present (Table 27.9). In addition, if such infants have chronic pooling of secretions in their upper airway, they will be mucousy with rattling, noisy respiration, often coupled with respiratory distress due to obstruction of the airway by secretions. Widespread conducted sounds, therefore, are often heard on auscultation of the chest.

After a massive regurgitation or vomit which triggers an episode of apnoea, cyanosis and bradycardia, but which has been promptly and efficiently dealt with (see below), many neonates show no abnormal physical signs 10–15 minutes later. In these babies, the clinical features suggesting that inhalation pneumonia has actually occurred are the non-specific ones of respiratory distress (p. 476). In a neonate with pre-existing lung disease, respiratory function deteriorates. In both groups, crepitations and rhonchi may be heard on auscultation.

Investigations

In the baby who rapidly reverts to normal and shows no signs of respiratory compromise 15–30 minutes after the episode, it is still advisable to do a CXR. A new area of consolidation, particularly in the right upper lobe, is very suggestive of inhalation, but more generalised and non-specific changes may occur. In either the chronic situation or following a single severe episode, if the baby has the signs of respiratory disease he or she should be investigated for infection (Ch. 39.2). Measuring the electrolytes, blood sugar and calcium is indicated in all babies and may identify a cause for a convulsion.

Treatment

The vomiting episode

When the baby is found, the mouth, nose and pharynx should be quickly and effectively sucked out. If the infant has become cyanosed, oxygen should be given by mask. Most babies respond briskly at this stage and no further treatment is required other than the evaluation outlined above. If the baby does not respond promptly, the airway should be cleared using a laryngoscope and inhaled material aspirated under direct vision. This should always be done if the episode is so severe that the baby remains apnoeic or intubation is required for resuscitation.

General management

Oxygen

Sufficient oxygen should be given to keep the P_{aO_2} in the normal range. If the aspiration has been severe, or it complicates pre-existing lung disease in a small preterm baby, the episode may trigger apnoea or cause such severe pneumonitis that the baby will require IPPV.

Physiotherapy

If there are copious secretions following inhalation, or if the CXR shows an area of consolidation, then 4-hourly physiotherapy should be given to encourage drainage from the affected region. The baby should also be nursed in the position that optimises drainage from the affected lobe.

Feeding

In most babies it is wise to stop oral feeds for 24–48 hours after an episode of aspiration/inhalation. In the preterm neonate, recourse to intravenous feeding may be necessary. In the term baby, once the tachypnoea has settled, oral feeding can be restarted unless there is some chronic problem, in which case a period of nasogastric feeds will need to be used.

Antibiotics

Until the cultures are negative, it is impossible to be sure that the whole episode was not triggered by infection. As a consequence, broad-spectrum antibiotic cover should be given, usually

flucloxacillin and an aminoglycoside (Ch. 39.2). Antibiotics should be continued for at least 5–7 days or until the baby is clinically much improved if there are marked CXR changes or the neonate required IPPV, even if the cultures are negative.

Morbidity and mortality of aspiration pneumonia

This is dependent on the underlying pathology, since the lung disease following inhalation per se is rarely, if ever, fatal. Babies with persistent failure to suck or swallow secretions after severe birth asphyxia and those with congenital neurological problems have a guarded prognosis on the basis of their underlying defects. Most babies with a structural defect do well with appropriate surgery, but there remains an appreciable mortality with laryngotracheo-oesophageal cleft (p. 610) or Pierre Robin syndrome (p. 605). For the baby whose problems are due to immaturity, the outlook is excellent, since it can be anticipated that the lung disease will respond to the therapy outlined, although some infants may develop BPD and have a prolonged convalescence.

Pulmonary haemorrhage

This condition is a form of fulminant lung oedema with leakage of red cells and capillary filtrate into the lungs. It must be differentiated from the common occurrence of a small amount of blood-stained material aspirated from the ETT of a ventilated baby as a result of trauma. Pulmonary haemorrhage occurs most commonly in babies weighing <1500 g, who often have a PDA (Garland et al. 1994).

Incidence

The incidence of pulmonary haemorrhage in infants with a birth-weight less than 1500 g, treated with surfactant, was reported to be 11.9% (Pandit et al. 1999).

Aetiology

Massive pulmonary haemorrhage (MPH) represents the extreme end of the spectrum of pulmonary oedema in the neonate. This has four main causes (Bland 1982) (Table 27.10), which all increase fluid leak into the pulmonary interstitium and thus elevate pulmonary lymphatic flow. Although intra-alveolar fluid may appear at an early stage of interstitial oedema (Snashall 1980), pulmonary oedema usually occurs as lung interstitial fluid rises and fluid leaks into the alveoli because the alveolar epithelium either has been damaged or becomes leaky owing to distension by the interstitial fluid. The first change is a rise in pulmonary capillary pressure; this causes an increase in interstitial fluid, which eventually leaks into the alveoli through holes in the epithelium. Initially these holes are large enough to allow passage of molecules such as albumin, but small enough to retain molecules such as IgG, IgM, and fibrinogen, and the majority of red cells. As the changes become more marked, the holes in the endothelium and epithelium increase in size and larger molecules leak through. In most cases, the amount of blood lost is small and the haematocrit of the lung effluent is less than 10%. MPH can occur following severe birth depression and in infants with hydrops due to rhesus haemolytic disease, left heart failure, congenital heart disease, sepsis, hypothermia, fluid overload, oxygen toxicity and haemostatic failure. Infants who are small for gestational age are more likely to suffer a pulmonary haemorrhage (De Carolis et al. 1998), the association being independent of other factors (Finlay and Subhedar 2000). In

Table 27.10 Causes of pulmonary oedema in the neonate

INCREASED PULMONARY MICROVASCULAR PRESSURE	REDUCED INTRAVASCULAR ONCOTIC PRESSURE	REDUCED LYMPHATIC DRAINAGE	INCREASED MICROVASCULAR PERMEABILITY
Heart failure	Prematurity	Pulmonary interstitial emphysema	Sepsis
Hypoxia	Hydrops	Pulmonary fibrosis	Endotoxaemia
Transfusions	Fluid overload	Raised central venous pressure	Emboli
Intravenous fat	Hypoproteinaemia		Oxygen toxicity
Increased pulmonary blood flow	Loss in gut		
Pulmonary hyperplasia	Loss from kidneys Malnutrition		
Reproduced with permission from Bland (1992).			

addition, the neonate with severe RDS on IPPV in a high oxygen concentration and heart failure secondary to a large pulmonary blood flow from a PDA may suffer an MPH (Garland et al. 1994; Evans and Kluckow 1999). Meta-analysis of the results of 29 trials (Raju and Langenberg 1993) demonstrated an association of MPH with synthetic, but not natural, surfactant use. Rescue surfactant therapy was not demonstrated to have a significant effect on MPH (Soll and Morley 2009), but prophylactic surfactant increased the risk (RR 3.28; 95% CI 1.5–9.2) (Soll 2000b). MPH is seen in babies with DIC, albeit rarely, but does not usually occur in babies with thrombocytopenia, haemorrhagic disease of the newborn or haemophilia. Following the marked clinical deterioration with MPH, however, it is not uncommon for secondary DIC to develop (Cole et al. 1973).

Pathology

The changes present in the lungs are dependent on the stage of the illness reached by the time of death. In deaths before 48 hours of age and in stillbirths, interstitial haemorrhage is common, but in deaths after 48 hours and following surfactant administration (Pappin et al. 1994), intra-alveolar bleeding dominates the clinical picture. The lungs are solid at postmortem and usually a deep reddish-purple colour; they are gasless and sink in water. Their pressure/volume characteristics will be those of low-compliance, surfactant-less lungs (p. 457). Hyaline membranes will often be present, since MPH frequently complicates primary RDS. As in RDS, there will be necrosis and desquamation of the alveolar lining cells. In cases which come to autopsy more than 48 hours after the haemorrhage, and particularly if the neonate survives for several days on IPPV, usually in a high oxygen concentration and at high pressures, the changes merge into those seen in severe BPD (p. 555).

Clinical features

The two striking clinical features of MPH are a sudden deterioration and usually the simultaneous appearance of copious bloody secretions from the baby's airway, either up the ETT or from the larynx and mouth in a non-intubated infant. The baby usually is hypotensive, pale and frequently limp and unresponsive, although term babies may occasionally be active and restless secondary to hypoxaemia, and 'fight' the ventilator.

Cardiac

The condition is commonly secondary to heart failure, hence the infant may have a tachycardia greater than 160/min and the murmur of a PDA is frequently heard (Garland et al. 1994). Other signs of heart failure, including hepatosplenomegaly and a triple rhythm, can occur. The presence of peripheral oedema may indicate heart failure, hydrops, hypoalbuminaemia or fluid overload. Hypotension is virtually always present, because of a combination of blood and fluid loss, heart failure and coexisting hypoxaemia and acidaemia.

Respiratory

Infants are dyspnoeic and cyanotic and auscultation of the chest reveals widespread crepitations with a reduction in air entry.

Differential diagnosis

Small amounts of blood coming up the ETT are usually due to trauma. A few babies may deteriorate clinically without apparent cause for an hour or two before the haemorrhage develops, but once copious blood-stained fluid appears from the airway, the diagnosis is self-evident. The underlying cause, however, should be established, since this will influence subsequent treatment.

Investigations

Haematological

Although the haematocrit of the oedema fluid is usually <10%, considerable quantities of blood may be lost, and the haemoglobin may fall to 10 g/dl or even lower. Cole et al. (1973) found that coagulation disturbances were not a regular feature of their patients prior to the haemorrhage, but DIC is not uncommon afterwards.

Biochemical

Affected preterm babies usually have the same problems as those with severe RDS. In particular, hypoglycaemia, hypocalcaemia, hypoalbuminaemia and renal failure should be sought and remedied.

Fig. 27.37 Widespread homogeneous opacification of the lungs in a baby with massive pulmonary haemorrhage. (Reproduced from Greenough et al. (1996).)

Chest X-ray

The CXR in the baby who has had a large MPH shows a virtual 'whiteout' (Fig. 27.37) with just an air bronchogram visible. This appearance is indistinguishable from severe surfactant deficiency and may be a reflection of the secondary surfactant deficiency that occurs following pulmonary haemorrhage. As the condition improves on IPPV, the changes may clear or merge into those of BPD. Rarely, a lobar pattern of consolidation is found, suggesting that the haemorrhage has occurred in just a part of the lung.

Bacteriology

The haemorrhage may be precipitated by sepsis. For this reason, an infection screen must always be taken immediately after the event. The baby's condition, however, will usually preclude performing a lumbar puncture (Ch. 39.2).

Blood gases

All components of arterial blood gas analysis deteriorate rapidly after the bleed. Hypoxia is severe, the P_{aCO_2} may increase to 10 kPa (75 mmHg) or more and there is usually a marked metabolic acidosis with a base deficit of at least 10 mmol/l. The combined respiratory and metabolic acidaemia may result in a pH of 7.10 or less.

Monitoring

The blood gases should be meticulously supervised. Clotting studies should be done daily until they normalise. A daily CXR should be performed because of the high ventilator pressures that are frequently required and the potential complications.

Treatment

Particular attention must be paid to maintaining the BP with blood transfusion, progressing to inotropes as necessary (Ch. 28). The

severe acidaemia should be corrected with intravenous base if IPPV and correction of the hypoxia and hypotension do not promptly return the pH and base deficit to an acceptable level. Underlying disorders must be treated. Heart failure due to anaemia in, for example, haemolytic disease should be treated by exchange transfusion with packed cells, aiming for a haemoglobin level of 13–14 g/dl. Asphyxial myocardial damage may need inotrope support (see below), and sepsis should be treated as outlined on Ch. 39.2.

Control of pulmonary oedema and heart failure

Fluid balance

Fluid input should be restricted to 60–80 ml/kg/24 h, particularly if there is a coexisting patent ductus. The BP can be sustained by judicious infusion of blood, but mainly by the use of inotropes.

Diuretics

These babies have left ventricular failure and pulmonary oedema. Furosemide (1 mg/kg) should be given as soon as possible after the haemorrhage and repeated as necessary, to treat fluid overload.

Intermittent positive-pressure ventilation

All babies with MPH should be intubated and ventilated. They usually have severe lung disease, and peak inflating pressures above 30 cmH₂O may be necessary. For this reason, and since mature babies in particular become very restless, neuromuscular blockade and sedation should be used routinely until the haemorrhage is controlled. During IPPV, a high PEEP (up to 6–7 cmH₂O) should be employed; in experimental studies this does not reduce the total lung water, but redistributes it back into the interstitial space, improving oxygenation and ventilation-perfusion balance (Pare et al. 1983; Malo et al. 1984).

Surfactant

Paradoxically, although surfactant may precipitate MPH (p. 459), after stabilising the baby on IPPV after the haemorrhage, a single dose of surfactant has been suggested to improve oxygenation (Pandit et al. 1995).

Patent ductus arteriosus

PDA is common in preterm neonates who develop MPH; use of prophylactic indometacin may reduce both complications (Clyman 1996). While the baby is critically ill, the use of indometacin or equivalent is contraindicated, but this should be reconsidered 24–48 hours later, once the coagulopathy is controlled and the hypoxia and acid-base disorders corrected.

Physiotherapy/suction

In the first few hours after the haemorrhage, there may be copious bloody secretions. Suction is required every 10–15 minutes in extreme cases, as there is a significant risk of the secretions clotting and blocking the airway or ETT. Physiotherapy, however, is not of proven value, and, as these neonates are extremely fragile, it should not be used as a routine in the early stages, instead relying on adequate humidification to keep the secretions sufficiently liquid that they can be sucked up the ETT.

Coagulopathy

The features of DIC are frequently present. Transfusion of platelets, however, is rarely required, but infusions of fresh frozen plasma are indicated and usually successful in promptly correcting the clotting deficiencies. After the first 24–48 hours when the baby has

become stable on IPPV, the acid–base disturbances have been corrected and septicaemia (if present) treated, the coagulation problems usually remit and further factor replacement is not usually necessary.

Antibiotics

Sepsis is a recognised cause of MPH; thus, antibiotics should be started after taking cultures. If the baby is already receiving antibiotics, it is recommended to broaden the spectrum to cover infection by staphylococci and *Pseudomonas* species.

Complications

These babies are susceptible to all the major complications of respiratory failure. High-pressure ventilation predisposes them to airleaks, and BPD is a common sequela (Pandit et al. 1999). At the time of their sudden collapse, they are susceptible to neurological damage and GMH/IVH (Ch. 40.5); the occurrence of cerebral bleeds may be doubled in babies who suffer pulmonary haemorrhage (Finlay and Subhedar 2000). The occurrence of seizures is increased in infants with pulmonary haemorrhage (Tomaszcwska et al. 1998).

Mortality

For many years this was regarded as a universally fatal condition (Garland et al. 1994). In the modern era of intensive care, survival is improved; but affected infants are the sickest and most immature and their mortality rate is of the order of 38% (Pandit et al. 1999).

Asphyxial lung disease/acute respiratory distress syndrome

Intrapartum asphyxia or severe lung injury may result in severe respiratory distress ARDS.

Aetiology

ARDS results from lung injury from a number of causes, including asphyxia, shock, sepsis, MAS and DIC.

Pathophysiology

Asphyxia damages pulmonary blood vessels, making them leaky, and this, plus the pulmonary oedema secondary to heart failure occurring as a result of asphyxial damage to the myocardium (Burnard and James 1961; Bucciarelli et al. 1977; Walther et al. 1985), may compromise surfactant function (p. 459). Severe metabolic acidosis can also depress myocardial contractility, again leading to heart failure, pulmonary oedema and tachypnoea (Beierholm et al. 1975; Watters et al. 1987). If the leak of protein-rich fluid on to the alveoli becomes large enough, ARDS develops, with epithelial degeneration, surfactant inhibition, interstitial cellular infiltration, pulmonary hypertension and eventually alveolar fibrosis (Royall and Levin 1988).

Metabolic acidosis stimulates hyperventilation (Javaheri et al. 1979). In the neonate, the chemoreceptors are sensitive to pH (Walker 1984; Navarete et al. 2003); the increase in respiration is more likely to be due to stimulation of peripheral chemoreceptors than medullary centres (Bureau et al. 1979).

Damage to the central nervous system may stimulate tachypnoea by two mechanisms. Firstly, the neural control of respiration may be damaged, resulting in hyperventilation. This is well recognised in older patients (Leigh and Shaw 1976). Neurologically damaged babies may hyperventilate to P_{aCO_2} levels of 2.5–3.0 kPa (19–23 mmHg) in the first few days after birth. Secondly, neurogenic pulmonary oedema may occur following any rise in intracranial pressure (ICP) or brain injury. It is primarily due to an increased pulmonary vascular permeability leading to interstitial pulmonary oedema, hypoxia and tachypnoea (Colice et al. 1984; Maron 1987). The mechanism is probably active in the newborn, and explains, for example, the sudden deterioration in respiratory function following a GMH/IVH, but may also be of importance in babies with HIE or subdural haemorrhage following birth asphyxia.

Asphyxia caused by cord occlusion with blood trapped in the placenta causing fetal anaemia (Shepherd et al. 1985; Vanhaesebrouck et al. 1987) and acute fetal haemorrhage from ruptured vasa praevia or following a large fetomaternal haemorrhage will result in the birth of a baby who is anaemic, shocked and acidotic (Raye et al. 1970). Chronic fetal anaemia due to rhesus disease or fetomaternal haemorrhage also produces babies with acidosis, anaemia and tachypnoea (Phibbs et al. 1972). The lowered buffering capacity of blood with a low haemoglobin will also potentiate the effect of metabolic acidosis on respiration (see above).

Clinical features

Some babies who suffer intrapartum asphyxia remain tachypnoeic for 24–48 hours after delivery (Thiebauld et al. 1984); less commonly, severe lung disease, ARDS (Faix et al. 1989), occurs.

Infants with ARDS are severely hypoxaemic. This is primarily a disease of term babies, who, within the first hour or two, usually present with tachypnoea of 100/min or more, rather than with retraction and grunting, although in some babies the clinical picture may be dominated by the neurological sequelae of asphyxia, and apnoea may occur (Thiebauld et al. 1984). The baby may be tachycardic and hypotensive with a triple rhythm, or have the systolic murmurs of tricuspid or mitral incompetence (Bucciarelli et al. 1977; Finley et al. 1979); if there has been severe myocardial damage, other signs of heart failure, crepitations and hepatomegaly may be found (Cabal et al. 1980).

Differential diagnosis

This is a diagnosis of exclusion in the neonate who has suffered intrapartum asphyxia. The CXR excludes complications such as pneumothorax and does not show the features of 'wet lung' seen in transient tachypnoea. Excluding sepsis, as always, is important, as GBS infection may masquerade as asphyxia (Peevy and Chalhub 1983).

Investigations

The blood gases should be measured on an arterial sample; babies with ARDS are severely hypoxaemic. Respiration is stimulated by the metabolic acidosis (base deficit >20 mmol/l, with a corresponding low pH), damage to the central nervous system or by lung receptors stimulated by pulmonary oedema; the P_{aCO_2} is usually <4 kPa (30 mmHg). Hypoglycaemia is common after asphyxia, as is DIC (Ch. 30); both should be remedied promptly if found.

A CXR is essential and will demonstrate diffuse pulmonary infiltrates. In severe cases there will be a 'whiteout' as in severe RDS.

Evidence of myocardial damage should be sought by performing an echocardiograph to assess ventricular function and an ECG should be obtained. The ECG may show changes of ST-segment depression and T-wave inversion if there is severe asphyxia (Caball et al. 1980; Setzer et al. 1980) but in lesser degrees of asphyxia there may only be slight flattening of the T-wave (Jedeikin et al. 1983). The level of the myocardial isoenzyme of creatine kinase may be raised (Primhak et al. 1985). If myocardial damage is present, much greater care has to be taken regarding use of bolus infusions.

Monitoring

A UAC is the preferred site for monitoring blood gases and BP. Affected babies are peripherally shut down, making clinical assessment of oxygenation impossible and arterial puncture difficult; frequent samples may be needed until the pH returns to normal.

Management

Surfactant administration can improve oxygenation in ARDS. It is most effective if given early and in larger doses than in RDS (Ogawa et al. 1999). In adults and children with ARDS, prone positioning has been shown to improve oxygenation (Curley et al. 2000).

Blood gases

The baby should receive sufficient warmed humidified oxygen to keep the P_{aO_2} above 8 kPa (60 mmHg). Prolonged high-pressure ventilation similar to that used for neonatal RDS (pp. 517–519) may be necessary (Faix et al. 1989). A high level of PEEP should be used to try and restore the FRC to more normal values; this will also increase the MAP level and hence oxygenation. An excessive amount of PEEP, however, will impair gas exchange by causing alveolar overdistension. High-volume strategy HFO can also improve oxygenation (Giffin and Greenough 1994), particularly in those patients who had a positive response to PEEP elevation (p. 521). HFJV has also been used with anecdotal success (Pfenninger et al. 1991). Inhaled NO has been used in patients with ARDS to improve oxygenation (Demirakca et al. 1996).

Metabolic acidaemia

Term neonates can recover spontaneously and quickly from pH levels of 7.10–7.15 and base deficits of >15 mmol/l (Daniel et al. 1966; Sykes et al. 1982; Spencer et al. 1993). For this reason, immediately after delivery, expectant treatment of uncomplicated metabolic acidaemia is justified if the pH is above 7.10, but an arterial gas should be checked 30–60 minutes later to ensure that spontaneous correction is taking place. If the pH is below this value, or the infant has heart failure attributed to acidaemia, then the pH should be corrected to 7.30–7.40 using the standard formula (Ch. 35.2).

Hypotension and heart failure

These are two of the most serious complications of severe asphyxia, as they are associated with secondary ischaemic injury to the central nervous system, myocardium (endocardial ischaemia), kidneys (renal failure) and intestine (NEC). They must, therefore, be corrected urgently. The general approach to hypotension outlined in Chapter 28 should be followed, taking great care with fluid balance if the myocardium is compromised. In general, the fluid intake should initially be restricted to 40 ml/kg/24 h. If heart failure is present, furosemide should be given. IPPV with PEEP helps to control pulmonary oedema.

Anaemia

A haemoglobin <13 g/dl (PCV <40%) is an indication for transfusion in asphyxial lung disease. If there is coexisting myocardial asphyxial injury, the transfusion should be given slowly and carefully with a diuretic. In such a situation, if the haemoglobin level is <8–9 g/dl, the safest way of increasing it is with a single-volume exchange transfusion using packed red blood cells.

Hypoxic–ischaemic encephalopathy

The management of this is outlined in detail in Chapter 40, part 4.

Antibiotics

After collecting the appropriate samples to assess if the baby is infected, including a blood culture, broad-spectrum antibiotics, usually penicillin plus an aminoglycoside (Ch. 39.2), should be administered. Aminoglycoside levels must be carefully monitored, as these infants are at risk of renal dysfunction.

Prognosis

The mortality of ARDS is high (Pfenninger et al. 1991), particularly in those infants who develop secondary infection or do not respond to elevation of their PEEP level. Airleaks and infection are commonly seen in infants with ARDS.

Pleural effusions

Isolated

These are uncommon in the neonatal period. The incidence of primary fetal hydrothorax is estimated at one case per 15 000 pregnancies (Linder et al. 1988).

Aetiology

Pleural effusions diagnosed antenatally are frequently associated with chromosomal or congenital abnormalities (Nicolaidis and Azar 1990). Intrauterine (cytomegalovirus, toxoplasmosis, rubella, adenovirus), perinatal (GBS and *Staphylococcus*) and postnatal (*Staphylococcus*) infection can all result in pleural effusions. Isolated effusions are usually a chylothorax (p. 515). Approximately 9% of infants with MAS have pleural effusions; rarer associations are TTN, PPHN, heart failure and congenital myotonic dystrophy. Right-sided diaphragmatic hernia can be associated with a hydrothorax, which results from a fluid-filled peritoneal sac in the right side of the chest (Whittle et al. 1989). An effusion will develop following repair of CDH (Ch. 29.6). Trauma, for example by direct erosion of the inferior vena cava by a TPN catheter into the pleural space, can result in a pleural effusion (Leipala et al. 2001). A unilateral hydrothorax may also occur if a central venous catheter migrates into the pulmonary vasculature (Madhavi et al. 2000). Pleural effusions are usually part of a generalised oedematous state (hydrops fetalis); an isolated fetal pleural effusion can progress to generalised hydrops.

Clinical signs

Infants with large effusions are frequently difficult to resuscitate as, antenatally, the pleural effusion may have prevented normal lung growth. In infants with underlying pulmonary hypoplasia, there will be a reduced pulmonary vascular bed and the babies will have PPHN. On examination, the trachea and mediastinum will be

Fig. 27.38 Chest X-ray demonstrates a right pleural effusion. Antenatally, the infant was hydropic with bilateral pleural effusions; pigtail catheters were inserted bilaterally (with successful drainage on the right) and are still in situ, shown by the two radiopaque dots on each side of the chest.

shifted to the contralateral side and the ipsilateral lung will be dull to percussion with absent breath sounds. Small effusions may be asymptomatic and diagnosed incidentally on a chest radiograph.

Diagnosis

Antenatally, pleural effusions are detected by ultrasonography and should be suspected in fetuses whose mothers have polyhydramnios (Pijpers *et al.* 1989). Postnatally, on the CXR there may be a 'whiteout' on the affected site (Figs 27.38 and 27.39), but if the pleural effusion is small, it is important to remember that fluid will collect in the most dependent parts of the chest, around the lateral chest wall or the diaphragm (Figs 27.40 and 27.41).

Differential diagnosis

At birth, the presentation of a large effusion is similar to that of CDH (Ch. 27.6), but there are no bowel sounds in the chest. The CXR appearance may be confused with an eventration or atelectasis.

Treatment

Antenatally, pleural effusions are drained either intermittently by thoracocentesis (Petres *et al.* 1982) or continuously by a thoraco-amniotic shunt (Booth *et al.* 1987). Indications for antenatal drainage include the development of hydrops and mediastinal shift with a unilateral effusion. At birth, infants with large pleural effusions require active resuscitation by intubation and positive-pressure ventilation (Pijpers *et al.* 1989). Thoracocentesis may also be required to achieve effective ventilation and this may also be necessary later in the postnatal period. See Chapter 44 for details of the technique.

Fig. 27.39 Bilateral pleural effusions. Note the presence of a pigtailed catheter on the right side of the chest; this was placed antenatally.

Fig. 27.40 Small pleural effusion. Chest X-ray in the erect position: note obliteration of the right hemidiaphragm. (Reproduced from Greenough *et al.* 1996.)

Aspirated fluid should always be sent for cytology to determine the lymphocyte count, and for biochemical and microbiological analysis. If the effusion is due to infection, the fluid will have a high protein content, with neutrophils present, and organisms may be isolated. The fluid should also be sent for cytological examination; a high lymphocyte count indicates a chylothorax. If a chest tube is

Fig. 27.41 Small pleural effusion. Supine X-ray showing a rim of fluid. (Reproduced from *Greenough et al. (1996).*)

used to drain a pleural effusion, it is important to ensure that the tip does not abut the mediastinum, as this increases the risk of phrenic nerve injury (*Williams et al. 2003*).

Prognosis

Antenatally diagnosed pleural effusions, particularly if present prior to 32 weeks of gestation, have a mortality rate as high as 55% (*Hagay et al. 1993*). Bilateral fetal pleural effusions are frequently associated with pulmonary hypoplasia. Postnatally, effusions persisting for more than 3 days increase the risk of chronic oxygen dependency (*Long et al. 1984*).

Chylothorax

Incidence

One in 10000 deliveries and one in 2000 neonatal intensive care admissions were reported to have a chylothorax (*Van Aerde et al. 1984*).

Aetiology

Chylothorax may occur spontaneously or be associated with lymphoedema due to congenitally abnormal lymph vessels in conditions such as Turner or Noonan syndrome or congenital lymphangiectasia. In the last condition, there is diffuse dilatation of the interlobular and subpleural lymphatics. A congenital abnormality in the lymphatic system at the level of the thoracic duct below or above the fifth thoracic vertebra leads to a right- or left-sided chylothorax (*Van Aerde et al. 1984*). It can be associated with foregut malformations and extralobar sequestration. Rarely, trauma to the thoracic duct at delivery by hyperexpansion of the spinal column in association with increased venous pressure during birth results

in a chylothorax, but more commonly it is a complication of certain types of cardiac surgery (repair of coarctation of the aorta or ligation of a PDA) or repair of a congenital posterolateral diaphragmatic hernia (*Mercer 1986*). Another iatrogenic cause is superior vena caval (SVC) obstruction in patients who have had venous catheterisation for TPN (*Amodio et al. 1987*).

Clinical signs

Unusually, chylothoraces result in hydrops, owing to impairment of venous return by cardiac and vena caval compression and/or loss of protein into the pleural space. In 50% of cases, chylothoraces present in the first week with symptoms as described under isolated pleural effusion. Typically, the lesion is right-sided. Chronic chylothorax may be associated with hypovolaemia, hypoalbuminaemia, hyponatraemia and weight loss. Such patients are immunocompromised owing to loss of lymphocytes and humoral antibodies.

Diagnosis

In an unfed infant, the fluid obtained at thoracentesis is clear, yellow and contains large numbers of lymphocytes (20–50 per high-power field). Lipoprotein electrophoresis demonstrates a high triglyceride and a low cholesterol level. Once the infant is milk-fed, the fluid will become chylous, clearing once a medium-chain triglyceride formula is introduced. Chylothorax associated with SVC obstruction should be suspected in infants with swelling of the face, neck and upper extremities; ultrasonography will confirm the presence of fluid in the chest and the position of the catheter tip. Doppler ultrasonography will identify the SVC obstruction.

Treatment

Chylothoraces may need to be drained antenatally (see above). Postnatally, many cases respond to a single thoracentesis, as this results in lung expansion tamponading the defect and preventing further pleural fluid formation. If the fluid reaccumulates, drainage is required and the baby should be fed with a milk containing fat only in the form of medium-chain triglycerides. In the gut, long-chain fatty acids pass into the lymph as chylomicrons after being re-esterified to triglycerides, before entering the venous network, whereas medium-chain fatty acids pass directly into the portal venous blood. Pregestimil or Pepti-Junior can be tried, but a semi-elemental milk may be required and should be continued for at least 2 weeks after the effusion has disappeared (*Hashim et al. 1964*; *Brodman et al. 1974*; *Puntis et al. 1987*). Rarely, in non-responsive cases, TPN should be used. Pleural abrasion, ligation of the thoracic duct and pleurodesis are possible options for those chylothoraces that fail to respond to medical management (*Andersen et al. 1984*; *Puntis et al. 1987*).

Prognosis

This condition usually resolves, but the mortality rate has been suggested to be as high as 60% for bilateral chylothoraces (*Carmant and Le Guennec 1989*).

Haemothorax

Aetiology

Trauma with damage to the arteries alongside the ribs from misplacement of a chest drain to drain a pneumothorax is the commonest cause of a neonatal haemothorax; it can also occur at

thoracic surgery. Rare causes include clotting abnormalities (Grausz and Harvey 1967), penetration of the fetal thorax at amniocentesis (Achiron and Zakut 1986), spontaneous rupture of a PDA and arteriovenous malformations.

Diagnosis

The CXR will demonstrate a 'whiteout', and a radioisotope lung scan can identify an underlying arteriovenous fistula.

Treatment

Resuscitation by urgent transfusion of blood and clotting factors may be required. Surgical intervention should be considered if a large blood vessel has been traumatised.

Management of neonatal respiratory failure

Oxygen therapy

Supplementary oxygen therapy

In mild to moderate respiratory disease, all that is usually required to keep the baby's P_{aO_2} at 8–12 kPa (60–90 mmHg) (Appendix 7) is the administration of warmed humidified supplementary oxygen. Additional support by CPAP or IPPV is indicated only if a satisfactory P_{aO_2} cannot be achieved in 60–80% oxygen in a headbox, or at lower inspired oxygen concentrations if there are other features of respiratory failure. To avoid sudden changes in the inspired oxygen concentration such as when the incubator doors are opened, the oxygen should be given into a Perspex box placed over the baby's head and shoulders (headbox). The concentration of oxygen administered should be measured by an analyser placed near the baby's mouth. This form of therapy is frequently sufficient for preterm babies more than 30 weeks of gestational age with RDS, all babies with minimal respiratory disease and most with TTN (p. 485). The occasional mature baby with RDS and most cases of meconium aspiration can also be managed with headbox oxygen, even though they may require concentrations of up to 80% for 72 hours or more, providing they do not develop other signs of respiratory failure.

A system for automated adjustments in the fraction of the inspired oxygen concentration to maintain the oxygen saturation level within the intended range has been shown to reduce hyperoxaemia (Claire et al. 2009).

Nasal cannula-administered oxygen

In babies requiring prolonged oxygen therapy for BPD, administration of oxygen by nasal cannula allows the baby to be picked up and cuddled and bottle- or breastfed. It is, however, difficult to assess the concentration of oxygen administered to such babies. Purpose-built double cannulae or an 8 FG feeding catheter cut to length and inserted 2–3 cm into one nostril can be used. Correct fixation of the catheter to the nostril is important to prevent restricting the flow rate, accidental displacement and excessive advancement of the catheter, which has been associated with gastric rupture (Cigada et al. 2001). A humidified high-flow nasal cannula (HFNC) is now used in some centres as an alternative to CPAP; usually flow rates of less than 2 l/min are used (see below). The potential reasons for the increased use are ease of administration, perceived

improved tolerance and minimal nasal trauma compared with nCPAP (Shoemaker et al. 2007).

Oxygen toxicity

Oxygen is toxic to tissues because it forms free radicals, such as superoxide (O_2^-) and hydroxyl (OH^\cdot) (Kelly and Lubec 1995). The neonate is exposed to complex physiological and pharmacological stresses from these agents (Smith et al. 1993; Saugstad 1996). If adults are exposed to even a few hours of pure oxygen, they develop tracheitis and reduced tracheal mucus velocity. After about 16–24 hours, they experience chest discomfort and cough. During the first 24 hours, there is a significant alveolar–capillary leak of protein (Davis et al. 1983). Dyspnoea develops after a further 24–48 hours (Jackson 1985). If pure oxygen exposure is continued for 3–4 days, animals develop a fatal lung disease with oedematous alveolar walls, interstitial haemorrhage, atelectasis (Clark and Lambertsen 1971) and type II cell hyperplasia (De Los Santos et al. 1987). Surfactant is depleted in the early stages of oxygen exposure, with a reduction in both DPPC and PG levels (King et al. 1989), which continue to fall after the animal is removed from 100% oxygen (Holm et al. 1987; Demirakca et al. 1996). Another deleterious effect of breathing pure oxygen is that all the nitrogen is washed out of the alveoli; as oxygen is much more rapidly taken up by pulmonary capillary blood than is nitrogen, this predisposes to atelectasis. Pulmonary alveolar macrophage function is significantly reduced in animals by exposure to more than 80% oxygen for at least 3 days (Sherman et al. 1988).

Exposure of the neonatal lung to a high inspired oxygen concentration in the presence of lung disease also causes damage, probably because the oxygen free radicals interact with lung cell lipids. Neonates, however, seem to be more resistant to pulmonary oxygen toxicity than are adults (Clark and Lambertsen 1971). This resistance is dependent on the presence in the tissues of antioxidant enzymes such as superoxide dismutase, catalase and glutathione peroxidase. In the term lung, the cells, including type II pneumocytes, are able rapidly to switch on antioxidant enzymes after birth (Frank et al. 1978; Keeney et al. 1992), an effect that may be stimulated by epidermal growth factor (Price et al. 1993), but this is less efficient in the preterm lung (Loo et al. 1989; Frank and Sosenko 1991; Keeney et al. 1993). The level of antioxidant enzymes and the resistance of the lung to hyperoxia are increased at term by prenatal maternal and postnatal treatment with dexamethasone (Davis and Whitin 1992; Frank 1992). In preterm animals, the postnatal increase in enzymes and oxygen resistance may be absent (Keeney et al. 1993; Sosenko et al. 1995). Administration of surfactant protects against oxygen toxicity (Huang et al. 1995; Piantadosi et al. 1995).

Although 100% oxygen clearly damages the lungs, the danger of lower oxygen concentrations to the human neonate is much less clear. In adult humans, oxygen concentrations less than 60% rarely do harm, and exposure to between 50% and 90% resulted in limited damage (Klein 1990). In mature rabbits, exposure to 60% oxygen for 3 weeks caused alveolar interstitial oedema, but increased surfactant production (Holm et al. 1987). Rats kept in 60% oxygen for 2 weeks had small lungs with parenchymal thickening (Han et al. 1996). Studies in neonatal baboons suggest that exposure to a high oxygen concentration even without IPPV is damaging (DeLemos et al. 1987a).

Administration of 100% oxygen to babies is never justified, as, with large shunts, the increase in P_{aO_2} achieved by increasing from 90% oxygen to 100% oxygen is trivial and is not worth the risks of both oxygen toxicity to the lung and the atelectasis that results from nitrogen washout.

Assisted ventilation in the newborn

Continuous positive airway pressure

CPAP is a positive distending pressure applied continuously. The aim of CPAP is to hold the alveoli and airways open and prevent them collapsing during expiration. The major benefit of CPAP is that it stabilises the ribcage, reducing chest wall distortion during inspiration and consequently increases the efficiency of the diaphragm (Shaffer et al. 1978). It regularises the respiratory rate, which usually falls because of stimulation of the Hering–Breuer reflex, and results in an increase in inspiratory time and tidal volume. There is an increase in the FRC in proportion to the level of applied pressure; some alveoli, however, will be overdistended, resulting in a fall in dynamic compliance (Moomjian et al. 1981). If too small a diameter tube is used to administer the CPAP, the work of breathing may increase as a result of the increased effort required to overcome the resistance of the tube (Le Souef et al. 1984).

Continuous positive airways pressure delivery

CPAP was initially given through an ETT (Gregory et al. 1971), but, in an attempt to avoid the hazards of intubation, many other devices have been used, including Gregory's original headbox, face chambers and negative-pressure chambers. These devices have mostly been abandoned. Facemask CPAP has a high complication rate (Gregory 1986) and thus is not recommended. The mask must be applied firmly to the face to prevent gas leaks and maintain the pressure and this can distort the baby's face; furthermore, the apparatus holding the mask in place must be strapped tightly around the back of the head, which can distort its shape. In early series, pressure necrosis and even GMH/IVH or cerebellar haemorrhage were reported (Pape et al. 1976). It is difficult to use a nasogastric tube with facemask CPAP because this breaks the seal; yet, without the nasogastric tube, the stomach cannot be easily aspirated and gaseous abdominal distension results. The presence of the facemask also makes it difficult to tend to the baby's mouth and nose. CPAP is now usually delivered to the baby through either a pair of tubes inserted into both nostrils or a single tube into one nostril. An alternative device, described by Benveniste et al. (1976), applies a jet of gas near to the exit of the curved attachment for the prongs in a way that mimics the actions of an expiratory valve and thus applies CPAP. This device has been widely used in the Scandinavian studies of CPAP in RDS (Jacobsen et al. 1993; Kamper et al. 1993). The method of nCPAP delivery used influences outcome. For example, there is a variation in the resistance to flow with the different nCPAP devices; the resistance is lowest in devices with short double prongs. That finding may explain why meta-analysis of the results of two studies demonstrated that short binasal prongs were more effective at preventing reintubation than were single nasal or nasopharyngeal prongs (De Paoli et al. 2002).

CPAP can be delivered using an underwater seal (de Klerk and de Klerck 2001); if the bubbling is vigorous, the baby experiences vibration of the chest at frequencies similar to those experienced during HFOV (p. 523). During 'bubble' CPAP, the column of water in the expiratory limb generates CPAP equal to the length of the tube that is immersed under water. In a small randomised trial of infants ready for extubation, gas exchange was maintained despite a significant reduction in minute volume during 'bubble' CPAP, suggesting that the chest vibrations may have contributed to gas exchange. In comparison with historical controls, however, ROP (grades I and II) was commoner in infants supported by bubble CPAP (Nowadzky et al. 2009). In a crossover trial (Morley et al. 2005) of high- versus slow-amplitude bubbling, no differences were

found with regard to oxygen saturation or transcutaneous carbon dioxide levels. Variable-flow nCPAP has been reported to be associated with better lung recruitment than with either continuous flow nCPAP via nasal prongs or continuous flow nCPAP via modified nasal cannulae (Courtney et al. 2001) and the work of breathing was lower with variable flow CPAP (Pandit et al. 2001). Those beneficial effects may be due to gas entrainment by the high-velocity jet flows; lung overdistension, however, may occur in infants with mild disease if CPAP levels greater than 6 cmH₂O are used with variable flow CPAP. In one trial (Gupta et al. 2009b), however, bubble CPAP was equally as effective as variable flow CPAP delivered by the Infant Flow Driver and, indeed, the extubation failure rate was significantly lower with bubble CPAP in infants ventilated for less than 14 days (Gupta et al. 2009b).

During bi-level CPAP two alternating levels of CPAP are delivered; the theoretical benefits are that the switching between CPAP levels might recruit unstable alveoli, the delta pressure generates a tidal volume and some of the respiratory work is unloaded. In a small randomised trial, bi-level nCPAP compared with nCPAP was associated with better respiratory outcomes and shorter duration of respiratory support (Lista et al. 2010).

HFNC delivers CPAP, usually at low levels. It is attractive in that trauma to the nose may be reduced by the use of smaller nasal cannulae than are used during CPAP, but there may be desiccation of the nasal mucosa with associated bleeding and airway obstruction if non-humidified HFNC is employed (Finer and Mannino 2009). The current delivery systems may not prevent excessive pressure delivery to the infant's airway and this may result in lung overexpansion (Finer and Mannino 2009), and the presence of a leak of 30% can reduce the delivered pressures to less than 3 cmH₂O (Lampland et al. 2009). Appropriately powered randomised trials with long-term outcomes are required to determine if HFNC with known pressure delivery is more or less efficacious than current methods of delivering continuous positive airways pressure.

Continuous positive airways pressure settings

In relatively mature infants with acute RDS who have not received treatment with surfactant, CPAP pressures of 5–8 cmH₂O may be required; however, in immature infants in the recovery stage of their illness who have more compliant lungs, levels in excess of 2–3 cmH₂O may not be tolerated. It is important not to use too high a CPAP level, as this will cause lung overdistension, resulting in impairment of ventilation and carbon dioxide retention. CPAP and F_{iO_2} levels should be adjusted on the basis of blood gas analyses. If the neonate still has unsatisfactory oxygenation in 50–60% oxygen, he or she should be intubated and ventilated.

Hazards of continuous positive airways pressure

Traumatic injuries to the nose and face from the prong(s) can occur (Robertson et al. 1996), including distortion of the nose, flaring of the nose, circular distortion and columella nasal necrosis. Although these can be minimised by good nursing technique, they are not completely avoidable. Randomised comparisons have demonstrated similar rates of injury with binasal prongs, nasopharyngeal tube and mask CPAP (Buettiker et al. 2004; Yong et al. 2005) and the only significant risk factor for nasal trauma was the duration of CPAP (Yong et al. 2005). Nasal CPAP support at 24 hours of age was an independent predictive factor for early-onset septicaemia in a prospective study of 462 ELBW infants (Rønnestad et al. 2005). In addition, in a case-control study (Graham et al. 2006), nasal CPAP was significantly associated with Gram-negative blood stream infections. The increased risk of infection was suggested to be due to trauma to the nares, increasing ports of entry for bacteria

(Kopelman and Holbert 2003). These adverse effects emphasise the importance of remembering that use of nCPAP requires meticulous attention to the airway and frequent suctioning may be necessary. Rigorous training is required for success; the correct size prongs should be used and the neonate's neck should be properly positioned (de Klerk and de Klerck 2001).

Airleaks do occur in infants supported by CPAP (De Bie et al. 2002; Gurakan et al. 2002). In a non-randomised study (Makhoul et al. 2002), pneumothoraces developed more often in infants supported by nCPAP than in those supported by synchronised intermittent mandatory ventilation (sIMV). In the COIN trial (Morley et al. 2008), the incidence of pneumothorax was three times higher in the CPAP arm; there was no excess of severe ICH or PVL, but pneumothoraces with normal cranial ultrasound findings have been associated with increased adverse neurodevelopmental outcome (Laptook et al. 2005). nCPAP, then, should never be used in units without facilities for both the rapid recognition and drainage of a tension pneumothorax and the subsequent use of IPPV.

Clinical studies

When first introduced, CPAP was applied to babies requiring 50–60% oxygen to keep their $P_{aO_2} > 8$ kPa (60 mmHg). With increased familiarity, the technique was used earlier in babies with RDS, often when they needed no more than 35–40% oxygen to maintain an acceptable P_{aO_2} . Used in this way, it improved blood gases and seemed to cause more rapid recovery (Gregory et al. 1971; Baum and Robertson 1974; Boros and Reynolds 1975; Durbin et al. 1976; Allen et al. 1977). In early randomised controlled trials, however, the benefits of CPAP seemed to be small (Robertson 1976a, b) and problems were experienced, and the results of prospective trials of CPAP in babies with relatively mild lung disease suggested that treated babies did less well than controls (Han et al. 1987; Hauer et al. 1996).

Early CPAP is now used in many centres in preference to early intubation and IPPV (Avery et al. 1987; Jacobsen et al. 1993; Kamper et al. 1993; Gitterman et al. 1997; Linder et al. 1999). In non-randomised trials, its use has been associated with a reduction in the requirement for mechanical ventilation and in the incidence of BPD. Comparison with a historical control group demonstrated that use of CPAP rather than intubation and ventilation was associated with fewer procedures related to respiratory support and the amount of pain medication was significantly lower (Axelin et al. 2009). However, in a large randomised (COIN) trial, which included 610 infants born at 25–28 weeks of gestation, although infants randomised to CPAP had a lower risk of death or need for oxygen therapy at 28 days, there was no significant difference in the rates of oxygen dependency at 36 weeks postmaturation age and the pneumothorax rate was significantly greater in the CPAP group (Morley et al. 2008). The higher pneumothorax rate might be explained by use of 8 cmH₂O CPAP and/or the lower use of surfactant in the CPAP group (Morley et al. 2008). If early CPAP is used, many centres temporarily intubate the baby so that surfactant can be given (Verder et al. 1994), and administer the surfactant early rather than late (Verder et al. 1999). The INSURE (intubation–surfactant–treatment–extubation) method is a combination of early surfactant treatment and early extubation on to CPAP (Blennow et al. 1999). In one study (van den Berg et al. 2010), the INSURE procedure did not induce any perturbation of cerebral oxygen delivery and extraction, but electrical brain activity decreased for a prolonged time. Meta-analysis of six trials demonstrated that the INSURE approach compared with selective surfactant with continued ventilation in infants with RDS was associated with a significant reduction in BPD, need for mechanical ventilation and airleaks

(Stevens et al. 2007). A larger proportion of the infants in the early compared with the selective surfactant group, however, received surfactant and it is well documented that prophylactic/early surfactant versus selective/rescue surfactant once RDS is established reduces the incidences of BPD/death and airleaks and improves survival (see above). Subsequent studies (Sandri et al. 2010; SUPPORT Study Group 2010) suggest that use of surfactant in the delivery room and selective use of surfactant are as effective as prophylactic surfactant.

In a randomised trial (te Pas and Walther 2007), which included 207 prematurely born infants, early versus rescue nCPAP (i.e. if necessary after arrival on the NICU) was associated with a reduction in BPD. The early nCPAP group, however, additionally received a sustained inflation of 20 cmH₂O for 10 seconds using a nasopharyngeal tube and T-piece ventilator, whereas bag and mask inflation was used in the other group with inflation pressures of 30–40 cmH₂O. In a lamb model, six manual inflations of 35–40 ml/kg compared with no bagging resulted in poorer lung function (Björklund et al. 1997). Thus, it is possible that early nCPAP did not reduce BPD, but rather volutrauma in the delivery suite increased BPD in the other group.

CPAP is frequently used during the recovery stage of RDS to support neonates following extubation from the ventilator (p. 529) (Dimitriou et al. 2000). It is also helpful in the management of infants with recurrent apnoeic attacks (Ch. 27.4); nCPAP dilates the upper airway, which may explain its selective beneficial effects on mixed and obstructive apnoea (Gaon et al. 1999). CPAP may be beneficial in upper airway obstruction due to Pierre Robin syndrome or congenital laryngeal stridor, when nasopharyngeal CPAP may be preferable, with the tip of the nasal cannula passing through the posterior choanae into the upper pharynx (Heaf et al. 1982). nCPAP has been used effectively and with an acceptable safety margin during transportation of term and preterm neonates (Murray and Stewart 2008).

Nasal-delivered ventilatory modes

Experience of ventilatory modes delivered by nasal prongs is limited and there have been no large randomised trials to determine whether these techniques offer long-term advantages for neonates.

Nasal prong-delivered IPPV (nIPPV) appears to augment the beneficial effects of nCPAP in prematurely born infants with apnoea (Lemyre et al. 2002); but there were case reports of gastrointestinal perforation with this mode of respiratory support. Meta-analysis of three trials highlighted that use of nIPPV is associated with a significant reduction in extubation failure (Carlo 2008).

Synchronised nIPPV (snIPPV) has generally been delivered by the Infant Star with a synchronised intermittent mandatory ventilation box (StarSync, Infrasonics, San Diego, CA). The StarSync module provides thoracoabdominal synchronisation via the Graesby capsule placed on the abdomen (Bhandari et al. 2009). In a retrospective non-randomised study, involving analysis of data from 471 infants (242 supported by snIPPV), snIPPV was associated with a reduction in BPD in infants with birthweight 500–750 g, but not overall (Bhandari et al. 2009); there was no excess of gastrointestinal problems (Bhandari et al. 2009). In a smaller ($n = 41$) randomised study, post surfactant extubation to snIPPV compared with ongoing ventilation was associated with a lower rate of BPD/death, but no other differences in outcomes (Bhandari et al. 2007). Others (Kugelman et al. 2008), however, have reported that nIPPV in stable premature infants resulted in increased BP and discomfort.

HFOV has been delivered by nasal prongs in case series only (Van der Hoeven et al. 1998; Colaizy et al. 2008). One series resulted in

a reduction in carbon dioxide levels in some infants with a moderate respiratory acidosis on nCPAP (Van der Hoeven et al. 1998). In another, carbon dioxide levels were lower and pH was higher after 2 hours of nasal HFOV compared with CPAP support in preterm infants older than 7 days (Colaizy et al. 2008).

Continuous negative expanding pressure

This is an alternative way of providing distending pressure in which the infant's body is placed in a negative-pressure box from which the head protrudes and continuous negative external pressure (CNEP) in the range -4 to -10 cmH₂O is applied (Samuels and Southall 1989). In patients already ventilated, the peak and PEEPs are reduced by the level of negative pressure applied. Early attempts at CNEP were poorly tolerated, particularly in ELBW infants, because of difficulties in securing the infant and hypothermia. These problems have been overcome by specially designed neck seals (Samuels and Southall 1989) and providing a circulation of warm air. CNEP can, however, overdistend the lung and impair lung function in infants with BPD. The considerable technical challenges have meant that CNEP is not widely used in the UK.

Early studies (Outerbridge 1979) demonstrated that CNEP was associated with improvements in oxygenation; the best results were experienced in infants with severe RDS. In addition, respiratory rate decreased and, in infants with stiff lungs, compliance improved on CNEP (Gappa et al. 1994). In a randomised trial (Samuels et al. 1996), use of CNEP (-4 to -6 cmH₂O) was associated with a lower duration of oxygen therapy (18.3 versus 33.6 days), but there were trends towards an increase in mortality and cranial ultrasound abnormalities in the CNEP group. Follow-up at school age demonstrated no important differences in respiratory outcomes for those who had been treated with CNEP as infants, but the trial was not powered to detect such differences (Telford et al. 2007).

Intermittent positive-pressure ventilation

Indications

There are two absolute indications for starting IPPV:

1. sudden collapse with apnoea, bradycardia and failure to establish satisfactory ventilation after a short period of bag and mask ventilation
2. failure to establish adequate spontaneous ventilation in the labour ward after prompt and active resuscitation (Ch. 13.1).

The relative indications for intubation and IPPV apply to babies who are breathing spontaneously, but are clinically, or on the basis of blood gas results, showing signs of impending respiratory failure. These indications vary with the gestational age of the baby, the nature of the underlying disease and whether the major feature of the respiratory failure is carbon dioxide retention, hypoxaemia or recurrent apnoeic spells.

Most babies in impending respiratory failure fall into one of three clearly separate groups, which require different plans of action:

1. VLBW neonates <28 weeks of gestation and <1.00 kg. These babies may be ventilated from the time of resuscitation in the labour ward (Ch. 13.1). A small number of these infants establish adequate regular respiration after birth but subsequently develop signs of RDS. To prevent sudden collapse with its attendant complications and to give surfactant, such babies should be ventilated once they need more than 40% oxygen on CPAP to keep their P_{aO_2} <7–8 kPa (52–60 mmHg) or have a P_{aCO_2} >6–6.5 kPa (45–50 mmHg) with a pH <7.25.

2. Babies 1.00–1.50 kg at 28–32 weeks of gestation with RDS. Nasal CPAP may be sufficient support for infants whose P_{aCO_2} is 6.5–7.0 kPa (50–55 mmHg) but who maintain their pH >7.25 and have an oxygen requirement of less than 60%. If, however, CPAP does not result in a prompt improvement, that is, a reduction in supplementary oxygen requirement to less than 40%, such babies should be ventilated.
3. Relatively mature babies 1.50–2.50 kg and 33–36 weeks' gestation. These babies have a more rigid ribcage and better developed respiratory muscles than very immature babies, so are more able to sustain vigorous respiratory efforts and tachypnoea for some days. They may, however, tolerate CPAP badly, becoming distressed and irritable when the device is attached.

Other indications for IPPV in the neonatal period include:

- PPHN: for the neonate with primary PPHN or secondary pulmonary hypertension, intubation and control of the P_{aCO_2} within defined limits can be beneficial (p. 498)
- severe early-onset sepsis (Ch. 39.2)
- MAS
- MPH
- diaphragmatic hernia: these babies should be ventilated from birth (Ch. 27.6)
- HIE: hyperventilation to prevent cerebral oedema by keeping the P_{aCO_2} in the 3.0–3.5 kPa (22–25 mmHg) range (Ch. 40.4) is no longer justified, but sedation due to anticonvulsant drug administration often necessitates intubation and ventilation
- apnoea: the small preterm baby with recurrent apnoeas, not controlled by methylxanthines or CPAP, requires IPPV (Ch. 27.4).

Delivery

A continuous flow of gas is delivered and this distends the lung for a preset inflation time to a predetermined pressure. During expiration, the ventilator gas flow continues to deliver PEEP if required. Gas enters the lungs during the inspiratory time; the amount entering is determined by the set peak pressure and the gas flow rate. The latter should always be large enough to ensure that the preset peak pressure can be reached during the available inflation time. At a fast flow, the lungs are distended more quickly and the peak pressure is reached sooner, thereby creating a relatively square-wave inspiratory gas flow. When the desired pressure has been reached, the pressure-limiting valve opens and prevents any further rise. The longer the inflation time, the longer the lungs are held distended at this pressure. The higher the pressure is set, depending on the compliance of the lungs, the larger the volume of gas which enters the lungs, though this is limited in non-compliant lungs by the size of the leak around the ETT.

Peak inflating pressures. When starting a baby on IPPV, the peak inflating pressure should be adjusted to ensure adequate, but not excessive, chest wall expansion; in practice this usually equates to a delivered volume of approximately 6 ml/kg (Dimitriou and Greenough 1995b). Sufficient pressure must be used to achieve acceptable blood gases. Since high pressures/volumes are likely to cause a pneumothorax (p. 487) or lead to BPD (p. 552), the lowest possible peak pressure compatible with normal blood gases should be employed. In general, the starting pressures for a baby with respiratory distress should be about 16–18 cmH₂O. The peak pressure is then adjusted according to the blood gas results, which should be determined within 15 minutes of commencing mechanical ventilation. Underventilation produces a high P_{aCO_2} and a low

P_{aO_2} , and overventilation a low P_{aCO_2} and sometimes an excessively high P_{aO_2} .

PEEP. This acts like CPAP to hold the peripheral airways open during expiration. PEEP should always be used during ventilation, as it conserves surfactant on the alveolar surface, except in severe PIE or certain cases of overinflation (Wyszogrodski et al. 1975). If too high a PEEP level is applied, particularly if combined with a short expiratory time, the lung cannot deflate properly. This causes hyperinflation, a reduced tidal volume and compromised gas exchange, and the P_{aCO_2} rises accompanied by a fall in P_{aO_2} . Early studies demonstrated that a PEEP of about 5 cmH₂O, rather than no PEEP or much higher levels, improved oxygenation (Herman and Reynolds 1973; Memon et al. 1979); the mechanism was via the effects of MAP on lung volume and oxygenation. The results of subsequent studies suggested that babies with acute RDS or apnoea do not require more than 3 cmH₂O of PEEP (Fiascone et al. 1992; Greenough et al. 1992). Babies who have severe RDS which does not respond to surfactant can require higher PEEP levels to optimise lung volume (da Silva et al. 1994). Infants ventilated beyond the first week without cystic chronic lung disease have improved oxygenation at 6 cmH₂O (Greenough et al. 1992).

Mean airway pressure. There is a good correlation between the MAP level and oxygenation (Herman and Reynolds 1973; Boros et al. 1977), such that P_{aO_2} may be improved by increasing the inspiratory time, the level of PEEP or the peak inflating pressure, all three manoeuvres elevating MAP. Elevation of the PEEP level, however, is the most effective method of increasing lung volume and hence oxygenation. At a critical level, determined by the infant's lung function, further elevation of the MAP level can impair oxygenation. The MAP level can be calculated from various formulae, but they assume a square-wave inflating pressure and therefore overestimate the MAP. Such calculations are now rarely necessary as the MAP level is displayed on most currently available ventilators.

Ventilator rates. Historically, babies with RDS were ventilated at a ventilator rate that matched their respiratory rate, about 80–100/min, but this resulted in a high incidence of BPD (Reynolds and Taghizadeh 1974). Studies (Herman and Reynolds 1973; Boros and Campbell 1980; Reyes et al. 2006) then showed that if an I:E ratio of 1:2 was used, the P_{aO_2} was higher at ventilator rates of 30/min compared with 80/min. At a rate of 30/min, the P_{aO_2} was found to be higher if the inspiratory time was longer than the expiratory time (a reverse I:E ratio) and 5 cmH₂O of PEEP was employed. Those data were restricted to neonates with severe RDS. Nevertheless, by the late 1970s, ventilator rates of 20–40/min with long inspiratory times were being widely used in infants with all types of lung disease, with an incidence of pneumothorax and other forms of airleak of 35–40% (p. 486). Subsequently, faster rates were preferred. Heicher et al. (1981) found that they could ventilate babies at 60/min with inspiratory times of 0.5 seconds at lower peak inspiratory pressures and with better blood gases and fewer pneumothoraces than when rates of 30/min and inspiratory times of 1 second were used. Subsequently, it was demonstrated (Greenough et al. 1987b) that, when babies with RDS were kept at the same MAP, rates of 120/min produced an improvement in P_{aO_2} compared with rates of 30 and 60/min; the improvement resulted from the neonates breathing in synchrony with the ventilator. By increasing the ventilator rate as necessary up to 100/min, most neonates were induced to breathe in synchrony (Greenough et al. 1986; South and Morley 1986a) and thus had better blood gases (Greenough et al. 1987a), but whether synchrony decreased the pneumothorax rate was not investigated. Meta-analysis of randomised trials (Greenough et al. 2008) has demonstrated that high-frequency positive-pressure ventilation compared with conventional

mechanical ventilation (CMV) significantly reduced the incidence of airleaks. No advantages of rates in excess of 20–40/min have been demonstrated in infants born at term and in paralysed infants; it is important in such infants to keep the ventilator rate at 60/min or less to reduce the likelihood of gas trapping (Hird et al. 1990).

Inspiratory and expiratory times, I:E ratios. In the 1970s, I:E ratios of 2:1 or even 3:1 were applied, giving inspiratory times as long as 1.5 seconds. This increased the MAP and improved oxygenation, but the reverse I:E ratio, with a concomitant prolongation of the inflation time, was one of the factors that correlated with the high pneumothorax rate (Primhak 1983; Tarnow-Mordi et al. 1985). Subsequently, the average inspiratory and expiratory times in ventilated babies with RDS were demonstrated to be 0.31 seconds (SD 0.06 seconds) and 0.42 seconds (SD 0.13 seconds), respectively (South and Morley 1986b), i.e. an I:E ratio of approximately 1:1.3. Employing such a ratio with an appropriate rate for gestational age (Greenough et al. 1987b) resulted in many babies with RDS breathing in synchrony with the ventilator, with an attendant improvement in oxygenation. Similar studies have not been undertaken in very immature infants with mild lung disease who have received both antenatal steroids and postnatal surfactant therapy; but it is likely that such infants, if they have vigorous respiratory efforts, would be best ventilated with a physiological I:E ratio (i.e. a longer expiratory to inspiratory time) and a rate similar to their spontaneous respiratory frequency. An I:E ratio of 1:1 results in best gas exchange for babies ventilated beyond the first week after birth (Chan and Greenough 1994b).

Ventilator settings with pressure-limited ventilators (Table 27.11)

Babies with abnormal lungs

Initially guided by the baby's colour and chest expansion, the following initial ventilator settings are appropriate, providing the chest wall moves adequately, until the result of blood gas analyses is available (Table 27.12):

Pressure: 18–20/3 cmH₂O
Rate: 60/min
Inspiratory time: 0.3–0.4 seconds
Oxygen concentration: 60–80%

Table 27.11 Adjustments to conventional ventilation according to disease

RESPIRATORY DISEASE	VENTILATORY SETTINGS
Respiratory distress syndrome	Low positive end-expiratory pressure Rates 60–80/min
Meconium aspiration syndrome	Low positive end-expiratory pressure Long expiratory time
Pulmonary hypoplasia	Low positive end-expiratory pressure
Pulmonary airleak	Minimise peak inspiratory pressure
Pulmonary haemorrhage	High positive end-expiratory pressure
Pulmonary oedema	Long inspiratory times

Table 27.12 Adjustments to ventilator settings on the basis of blood gas changes

Low PaO_2	High $Paco_2$	Increase peak pressure, which will also increase mean airway pressure: in spontaneously breathing babies \uparrow rates may also work
Low PaO_2	Normal $Paco_2$	$\uparrow F_{iO_2}$; \uparrow MAP but maintain PIP (i.e. \uparrow PEEP or $\uparrow T_i$)
Low PaO_2	Low $Paco_2$	Consider alternative diagnosis, e.g. PPHN, sepsis, overventilation. $\uparrow F_{iO_2}$; \uparrow MAP; use vasodilators
PaO_2 normal	High $Paco_2$	\downarrow PEEP, \uparrow rate; keep MAP constant
PaO_2 normal	Low $Paco_2$	\downarrow rate; maintain MAP
PaO_2 high	$Paco_2$ high	Rare: check for mechanical problems, e.g. blocked tube, \downarrow PEEP, $\downarrow T_i$; \uparrow rate $\downarrow F_{iO_2}$
PaO_2 high	$Paco_2$ normal	\downarrow MAP (usually \downarrow PIP); $\downarrow F_{iO_2}$
PaO_2 high	$Paco_2$ low	\downarrow pressure, \downarrow rate, $\downarrow F_{iO_2}$ (see text)
PaO_2 normal	$Paco_2$ normal	Sit tight! Unless plan to wean

MAP, mean arterial pressure; PIP, peak inspiratory pressure; PEEP, positive end-expiratory pressure; PPHN, persistent pulmonary hypertension of the newborn.

Babies with normal lungs

For babies with primary neurological or myopathic problems, e.g. congenital myopathy (Ch. 40.7), fractured cervical spine, severe neurological depression due to birth asphyxia (Ch. 40.4), drugs (Ch. 26) or preterm babies with recurrent apnoea (Ch. 27.4), the initial ventilator settings should be:

Pressure: 15/3 cmH₂O

Rate: 20–30/min

Inspiratory time: 0.35–0.40 seconds

Oxygen concentration: 21–30%

Volume-targeted ventilation

During volume-targeted ventilation (VTV), a set tidal volume is delivered despite changes in the infant's respiratory function; this is achieved by servo-controlled changes in the inflating pressure. There are different forms of VTV (Sharma et al. 2007). During volume-controlled or volume-supported ventilation, the desired tidal volume is selected and the duration of inflation depends on the time taken for the volume to be delivered. During volume guarantee ventilation, a preset expiratory tidal volume is selected, but the preset inspiratory time determines the duration of inflation and the maximum pressure set by the clinician limits the maximum inflation pressure. There is also volume-limited ventilation, during which the pressure support for any inflation is aborted if the measured inspired tidal volume exceeds a preset upper limit. During volume control ventilation, there is a breath-by-breath servo-controlled flow, which is constant during inspiration so that the

required volume is delivered over the set inspiratory time. At the same preset ventilator settings, the Stephanie and VIP Bird ventilators deliver significantly lower peak pressures and tend to deliver lower MAPs than the Draeger and SLE. At a VTV level of 5 ml, the SLE and the VIP Bird deliver significantly shorter inflation times. The above differences relate to differences in the airway pressure waveforms delivered by the four ventilators. The VIP Bird had a less variable volume delivery, but this was always significantly lower than the preset volume guarantee level, but higher than the volume displayed by the ventilator (Sharma et al. 2007).

Clinical studies have demonstrated that the combination of volume guarantee and pressure support compared with sIMV improve infant-ventilator synchrony (El-Moneim et al. 2005) and reduce breath-to-breath variability (Bhandari et al. 2007). Meta-analysis of four randomised trials demonstrated that VTV was associated with lower rates of severe ICH and pneumothorax and the duration of ventilation (McCallion et al. 2005); the trial designs and the ventilators used, however, differed considerably. Subsequent trials have not shown such striking differences. In one (Cheema et al. 2007), volume guarantee halved the occurrence of hypocarbia but only in infants over 25 weeks of gestation; all the infants between 23 and 25 weeks of gestation had out-of-range P_{CO_2} results. In another trial, infants randomised to volume control ventilation met predefined success criteria sooner and had a shorter duration of mechanical ventilation, but there were no significant differences in other outcomes (Sinha et al. 1997). At follow-up, less of the volume control ventilation group in the latter trial (Sinha et al. 1997) required inhaled steroids/bronchodilators but neurodevelopmental outcome was similar (Singh et al. 2009). Comparison with HFOV demonstrated that volume guarantee was associated with both lower levels of lung inflammation and duration of oxygen dependency (Lista et al. 2008).

A problem with volume ventilation is that not all the tidal volume is delivered to the baby's lungs, as, with the onset of inflation, the pressure rises, compressing the gas in the ventilator circuit as well as in the baby. Furthermore, unless cuffed ETTs are used, as the pressure rises, there is a variable leak of gas around the ETT. As a consequence, the volume required to ventilate the baby cannot be calculated with accuracy. In addition, in an *in vitro* study, the tidal volume displayed by the ventilator underestimated that delivered due to endotracheal leakage depending on ventilator pressures (Mahmoud et al. 2009).

Levels of volume-targeted ventilation

Results from physiological studies have demonstrated that, within the tidal volume range, higher rather than lower levels of tidal volume are likely to be more beneficial. Higher levels of lung inflammatory markers were experienced at VTV levels of 3 rather than 5 ml/kg (Lista et al. 2006), 6 rather than 3 ml/kg reduced the duration of hypoxaemic episodes (Polimeni et al. 2006) and the work of breathing as assessed by the pressure-time product was lower in infants ventilated at 6 rather than 4 ml/kg in infants with acute (Patel et al. 2010a) or recovering from (Patel et al. 2009b) respiratory distress. The most appropriate tidal volume level will probably vary with postnatal age and disease type, as, despite use of permissive hypercapnia, tidal volume requirements increase with advancing postnatal age over the first 3 weeks after birth, probably reflecting the increase in alveolar dead space (Keszler et al. 2009).

Patient-triggered ventilation

PTV is a mode in which the patient's inspiratory efforts 'trigger' positive-pressure inflations.

Assist/control and synchronous intermittent mandatory ventilation

The initial triggered ventilation modes used in the 1980s were assist/control (A/C), otherwise known as synchronous IPPV (sIPPV) or now assist control ventilation (ACV), during which all of the infant's respiratory efforts could trigger positive-pressure inflations, and sIMV, during which the maximum number of breaths that could be triggered was determined by the preset sIMV rate.

Various triggering systems have been used. Their performance can be evaluated by their susceptibility to autotrigger, their sensitivity (the number of the baby's inspiratory efforts that are detected) and their trigger delay or response time (the delay between the sensor being activated and the ventilator inflating the baby). Autotriggering occurs if there is excessive condensation in the ventilator circuit, which can cause changes in flow or pressure, and if there is a large leak around the ETT.

During A/C or sIMV, it is important to limit the ventilator inflation time, or it may extend into the spontaneous expiration of the baby, resulting in asynchrony or even active expiration (Hird and Greenough 1990). In addition, a prolonged inflation time has been shown to reduce the triggering rate by stimulating the Hering-Breuer reflex (Upton et al. 1990). If, however, the inflation time is too short (0.2 second), the volume delivered by the ventilator is compromised (Field et al. 1985; Dimitriou and Greenough 2000). The optimum inflation time, therefore, appears to be between 0.3 and 0.4 seconds.

Clinical studies

ACV or sIMV, compared with conventional ventilation, in a series of physiological studies was associated with a lower rate of asynchrony (Bernstein et al. 1993), higher tidal volume and improved blood gases (Cleary et al. 1995); additional advantages were reduced fluctuations of both BP (Hummeler et al. 1994) and cerebral blood flow velocity (Gournay et al. 2002). Meta-analysis (Greenough et al. 2008) of the results of randomised trials, however, demonstrated that the only advantage of ACV or sIMV was a significantly shorter duration of weaning, as the incidences of BPD, severe ICH and airleaks and the mortality rate were similar. Thus, on current evidence, use of ACV or sIMV cannot be recommended for infants with acute RDS. ACV, however, is useful in infants recovering from RDS; in a randomised trial it was shown to shorten the duration of weaning significantly (Chan and Greenough 1993b).

There have been no randomised comparisons of ACV and sIMV in RDS, but the results of three randomised trials suggest that ACV rather than sIMV is the more efficacious weaning mode (Chan and Greenough 1993a, 1994a; Dimitriou et al. 1995). Weaning involving reducing the sIMV rate below 20/min, compared with a reduction in the peak inflating pressures during ACV, was associated with a significantly longer duration of weaning (p. 529). In a randomised short-term physiological study, the work of breathing was higher when volume guarantee was combined with sIMV compared with ACV (Abubakar and Keszler 2005).

Pressure support ventilation

During PSV, the patient's inspiratory effort triggers the onset of a positive-pressure inflation and the end of the spontaneous inspiration dictates the termination of the inflation. PSV has been demonstrated (Dimitriou et al. 1998a) to reduce the asynchrony rate; it is important to determine whether this translates into a lower incidence of airleak. Pressure support increases total minute ventilation and stabilises breathing in proportion to the level of support provided between partial and full-pressure support (Gupta et al. 2009a). In a randomised trial of 107 ELBW infants, pressure support

compared with sIMV reduced the number of infants still ventilated at 28 days, and amongst those infants with a birthweight of 700–1000 g it was associated with fewer days of supplementary oxygen (Reyes et al. 2006). In a physiological study (Patel et al. 2009a), addition of PSV to sIMV using the same criteria as in the randomised trial (Reyes et al. 2006) was associated with a significant reduction in the work of breathing as assessed by the measurement of the transdiaphragmatic pressure time product. Those results further support the concept that weaning is best achieved by modes providing pressure support to every breath.

Proportional assist ventilation

During proportional assist ventilation (PAV), the applied ventilator pressure is servo-controlled throughout each respiratory cycle, based on a continuous input from the patient, such that the baby controls the timing, depth and airflow contour of the entire ventilator breath. In addition, negative ventilator resistance and elastance can be applied (unloading), to relieve the resistive and elastic work of breathing, respectively (Schulze et al. 1998). The clinician sets the level of unloading and this enhances the effect of respiratory muscle effort.

During PAV, it is essential that there is adequate back-up ventilation should the baby develop hypoventilation or apnoea. Other possible adverse effects include excessive resistive and elastic unloading, which result, respectively, in resonant oscillations and runaway ventilator pressures. It is also important to avoid using PAV with a major leak around the ETT, as the leak flow mimics inspiration and hence may cause the ventilator repeatedly to deliver inflations to the set upper pressure limit. In an in vitro study (Patel et al. 2010b), increasing unloading was matched by an inspiratory load reduction but, during unloading, delivered pressures were between 1 and 4 cmH₂O above those expected. Oscillations appeared in the airway pressure when the elastic unloading was greater than 0.5 cmH₂O/ml with a low-resistance model and 1.5 cmH₂O/ml with a high-resistance model and when the resistive unloading was greater than 100 cmH₂O/l/s. There was a time lag in the delivery of airway pressure of at least 60 ms. The impact of these problems needs careful evaluation in the clinical setting.

Clinical studies

In preterm infants, PAV compared with A/C and IMV, in a short-term physiological study (Schulze et al. 1998), allowed adequate gas exchange at lower MAPs. It is important to determine if PAV offers long-term advantages over other modes of ventilation in appropriately designed trials (Schulze et al. 1999).

Neurally adjusted ventilatory assist

During neurally adjusted ventilatory assist (NAVA), partial ventilatory assist is controlled by the electrical activity of the diaphragm (EAdi) (Sinderby et al. 1999), which represents the final neural output of the respiratory centres to the diaphragm. The pressure during inspiration during NAVA is delivered in proportion to the EAdi and this proportionality can be adjusted by the clinician. There is limited information regarding NAVA in infants; data from animal models suggest that, in comparison with PSV, NAVA was associated with better synchrony and a lower work of breathing (Beck et al. 2007).

High-frequency jet ventilation

HFJV is a modification of the technique initially developed to provide respiratory support during bronchoscopy. Frequencies between 60 and 600/min may be used. During HFJV, a

high-pressure source delivers gas in short bursts down a small-bore injector cannula; the tip of the cannula usually lies within the ETT, pointing towards the lung (Froese and Bryan 1987). The bursts of gas entrain additional gas from areas surrounding the jet cannula down the ETT; expiration is passive. In most studies, rates of 100–200/min have been used. In an animal model (Weisberger et al. 1986), a relatively narrow range of inspiratory and expiratory times was demonstrated to provide optimum HFJV. A significantly higher airway pressure gradient is necessary to maintain a constant tidal volume if the inspiratory time is shortened, and reduction in expiratory time below 170 ms results in air trapping. Most jet ventilators operate like constant-flow time-cycled ventilators and the pressure waveform is typically triangular, although pressure servo-controlled jet ventilators are available and produce a square pressure waveform. Keszler and Durand (2001) have described jet ventilators in detail. On HFJV, the PEEP is increased to optimise lung volume and a background IMV rate of 2–5/min employed to open up the alveoli on inspiration (Keszler and Durand 2001). During weaning, it is also important to maintain lung volume; thus, as with HFO, the F_{IO_2} is reduced before the MAP.

Clinical studies

HFJV has been used as a rescue mode of support to improve blood gas tensions in infants with respiratory failure unresponsive to conventional ventilation (Pokora et al. 1983); adequate blood gas tensions were achieved with lower peak inflation pressures (Carlo et al. 1984). It was also used with good results in babies with airleaks, in particular bronchopleural fistulae (Boros et al. 1985; Gonzales et al. 1987), PPHN (Carlo et al. 1989) and diaphragmatic hernia (Boros et al. 1985). The results of randomised trials, however, have been conflicting. In a small trial of 42 infants, no improvement in outcome with HFJV was demonstrated (Carlo et al. 1987), and in another study (Engle et al. 1997), although oxygenation improved in infants with PPHN, no long-term benefits were ascribed to HFJV use. Keszler et al. (1991, 1997) reported two positive trials: HFJV use was associated in the first (Keszler et al. 1991) with more rapid resolution of PIE, and in the second (Keszler et al. 1997) with a reduction in the incidence of BPD at 36 weeks and need for home oxygen. Another trial (Wiswell et al. 1996), however, was halted for safety reasons, as infants exposed to HFJV as opposed to CMV had higher rates of severe ICH (41% versus 22%) and PVL (31% versus 6%). Meta-analysis of three trials demonstrated that HFJV use was associated with a significant reduction in BPD, but a non-significant trend towards an increase in PVL (Bhuta and Henderson-Smart 2000).

Complications

HFJV use has been associated with a high incidence of necrotising tracheobronchitis (Mammel and Boros 1987), an ischaemic lesion resulting from intraluminal tracheal pressure compromising mucosal and submucosal blood flow. In HFJV, the lesions range from moderate erythema of the airway to severe necrotising tracheobronchitis with total tracheal obstruction (Boros et al. 1985). The high mean pressure and near-constant intraluminal pressure may be important factors in the pathogenesis of this problem (DeLemos et al. 1987b). Not all workers, however, have found a high incidence of necrotising tracheobronchitis, perhaps because of meticulous humidification (Carlo et al. 1987), but others have reported that HFJV causes more tracheal damage than IPPV (McEvoy et al. 1982; Ophoven et al. 1984) and that the longer the technique is applied, the more likely that necrotising tracheobronchitis will develop (Boros et al. 1977; Fox et al. 1984).

High-frequency flow interrupters

High-frequency flow interrupters (HFFIs) deliver small volumes of gas at high frequencies. A high-pressure gas source fed into a CPAP circuit immediately opposite the ETT connector is interrupted. These devices can be used at frequencies of up to 20 Hz (1200/min).

Clinical studies

HFFI use has been associated with improvements in blood gases in babies with PIE, and radiological resolution of the PIE (Fox et al. 1978; Gaylor et al. 1987). No long-term benefits of HFFI have been reported from randomised trials (Pardou et al. 1993; Craft et al. 2003).

Complications

Unlike HFOV (see below), neither HFJV nor HFFI incorporates an active expiratory phase and thus gas trapping may be experienced, particularly at fast frequencies. Tracheal necrosis has been experienced with HFFI.

High-frequency oscillatory ventilation

During HFOV, frequencies between 180 and 3000/min (3–50 Hz) may be used; however, in practice, frequencies of 10–15 Hz are most commonly employed. Unlike other forms of respiratory support, there is an active expiratory phase as well as an active inspiratory phase; this means that gas trapping is unlikely, even though very fast frequencies are employed. During HFOV, a volume generator feeds into a CPAP circuit close to the patient. The generator can be a piston, bellows or a loudspeaker driven by a generator and audio amplifier. Continuous flow is necessary to add fresh gas to the circuit and remove expired gas. HFOV may also be given at the same time as conventional ventilation (Murthy and Petros 1996), but there are no data to suggest such an approach has long-term benefit.

During HFOV, two volume strategies have been pursued: a low-volume strategy, in which MAP is limited with the aim of preventing damage due to barotrauma, and a high-volume strategy, in which MAP is elevated to promote optimum alveolar expansion and hence improve oxygenation. Comparison of the two strategies in animal models demonstrated that the high-volume strategy is less damaging to the lungs (McCulloch et al. 1988). An escalating recruitment manoeuvre, i.e. stepwise increases in MAP, was the most effective method of volume recruitment on initiation of HFOV in a piglet model (Pellicano et al. 2009). Volume delivery during HFOV is proportional to the product of the frequency and the square of the oscillatory amplitude (Slutsky et al. 1981). Early studies suggested that HFOV provided a tidal exchange considerably less than the baby's anatomical dead space (Froese and Bryan 1987). It was suggested that gas exchange occurred additionally by mechanisms distinct from those operating during conventional ventilation; these included bulk flow by convection, convective mixing between lung units (Pendelluft) and augmented diffusion (Chang 1984). It has more recently been demonstrated that infants are oscillated at a tidal volume similar to their anatomical dead space (Dimitriou et al. 1998b).

Management during high-frequency oscillatory ventilation

Oxygenation is influenced by the inspired oxygen concentration and the MAP, the latter controlling lung volume. If a high-volume strategy is used as a rescue support, then the infants should be transferred to HFOV at a MAP 2 cmH₂O higher than that on CMV (Chan and Greenough 1993c). The MAP is then gradually increased to optimise oxygenation. Infants with severe respiratory failure on

conventional ventilation often have very low lung volumes and an increase in MAP on HFOV of up to 10 cmH₂O may be necessary to maximise oxygenation (Dimitriou and Greenough 1995). The optimum MAP and the change in MAP necessary to optimise oxygenation are dependent on the severity of the infant's lung disease and lung volume. If too high a level of MAP is used, this will result in lung overdistension and deterioration in blood gases. It is thus important to increase the MAP in incremental stages, leaving sufficient time at each step for the lung volume to equilibrate; this usually happens within 10 minutes, but may take up to 20 minutes (Thome et al. 1998). Continuous monitoring of oxygenation should be employed; in an infant with atelectasis this will demonstrate an improvement in oxygenation when the MAP is increased. The MAP should then only be further increased once the monitoring demonstrates no further change in oxygenation, i.e. the lung volume has stabilised; such an approach will minimise the risk of overdistension. Closed endotracheal suctioning is usually performed without disconnection from the ventilator with the hope of maintaining lung volume. However, an *in vitro* study has demonstrated that airway pressures and tidal volumes were not maintained during closed suctioning with either HFOV or CMV (Kiraly et al. 2009).

Carbon dioxide elimination is dependent on the delivered volume, which is influenced primarily by the oscillatory amplitude, but also by the frequency and I:E ratio. On commencing HFOV, the oscillatory amplitude is increased until chest wall vibration is apparent, and then adjusted as needed to correct hypocapnia or hypercapnia. If an oscillator capable of delivering a constant volume is employed, oscillating at the resonant frequency of the respiratory system in RDS (between 12 and 24 Hz, 720–1440/min), this is associated with an increased volume delivery to the infant (Hoskyns et al. 1991).

The resonant frequency of the respiratory system in preterm infants with RDS remains remarkably constant in the early stages of their illness, despite large changes in static compliance (Lee and Milner 2000). Unfortunately, this does not apply to the majority of commercially available oscillators, whose performance is impaired at increased frequencies (Laubscher et al. 1996). Thus, altering the frequency from 10 to 15 Hz using such oscillators has very little impact on carbon dioxide elimination (Chan and Greenough 1994c). Reducing the frequency below 10 Hz, particularly with the Sensor Medics oscillator, however, results in a greater volume delivery (Laubscher et al. 1996) and thus this manoeuvre can be very useful to improve carbon dioxide elimination in a mature infant with severe respiratory failure. Increasing the I:E ratio from 1:2 to 1:1 on the Sensor Medics increases the delivered volume and hence carbon dioxide elimination (Dimitriou et al. 1999) and has not been associated with gas trapping in infants with respiratory failure (Alexander et al. 1993).

HFOV in animals suppresses spontaneous respiration; although this in part is explained by changes in blood gas tensions, this effect also appears to be related to stimulation of pulmonary mechanoreceptors; vagal fibres are stimulated continuously and to a greater extent during HFOV than with static lung inflation (Man et al. 1983). In humans, spontaneous respiration is reduced, but not usually inhibited (Chan et al. 1995); however, this rarely interferes with the effectiveness of respiratory support (HIFI Study Group 1989; Chan et al. 1995). Hence, we do not recommend routine neuromuscular blockade for infants supported by HFOV.

Early versus selective delayed surfactant administration resulted in a better outcome for infants supported by high-volume strategy HFOV (Plavka et al. 2002). In a randomised trial involving 43 infants, a smaller proportion of infants given early rather than delayed surfactant suffered the combined outcome of death

or supplementary oxygen requirement at 36 weeks' PCA (29% versus 64%) or had had an ICH (43% versus 82%) (Plavka et al. 2002).

Clinical studies

There have been many anecdotal reports of benefit using HFOV (Marchak et al. 1981) in babies with severe RDS (Chan et al. 1994), hypoplastic lungs, pneumonia, PPHN (Boynton et al. 1984), PIE (Clark et al. 1986) and diaphragmatic hernia (Karl et al. 1983). Use of HFOV enabled blood gas tensions to be maintained, with a lowering of MAP and resolution of PIE (Clark et al. 1986), and may be applied only to the affected side if selective intubation is employed (Rettwitz-Volk et al. 1993). Severe lobar emphysema may resolve on HFOV if a low-volume strategy is pursued (Kohlhauser et al. 1995). HFOV, however, is not a successful form of rescue respiratory support in all babies. Failure to improve oxygenation after 6 hours of treatment identifies those babies most likely to die (Chan et al. 1994; Paranka et al. 1995) or survive with disability (Cheung et al. 1997).

There have been two randomised trials of HFOV in infants with severe respiratory failure (Henderson-Smart et al. 2009). In term-born infants (Clark et al. 1992), HFOV was a more effective rescue support than CMV, but there were no significant differences in the requirement for ECMO or duration of ventilator or oxygen dependency between the two groups. In preterm infants (HiFO Study Group 1993), use of HFOV was associated with a significant reduction in new pulmonary airleak (RR 0.73, 95% CI 0.55–0.96), but a significant increase in ICH (RR 1.77, 95% CI 1.06–2.96).

Prophylactic trials in which infants have been randomised to receive HFOV or CMV in the first 24 hours after birth have been performed. The trials have differed with respect to administration of antenatal corticosteroids and postnatal surfactant, and the types of oscillator and conventional ventilator used. Meta-analysis of the results of those trials (Henderson-Smart et al. 2007) has demonstrated that HFOV had no significant effect on mortality, but was associated with a modest but significant reduction in BPD at term.

Complications

In an initial prospective randomised study (HIFI Study Group 1989), prophylactic use of HFOV in infants of birthweight between 750 g and 2000 g with respiratory failure due to RDS, pneumonia or PPHN was associated, worryingly, with a significant increase in the incidence of complicated GMH/IVH. The study design, however, has been criticised, as, in particular, a low-volume strategy was pursued. In one trial (Morielle et al. 2001), even though a high-volume strategy was used, a trend towards an increase in severe ICH was also noted, although this did not reach statistical significance when adjusted for differences in pregnancy-related hypertension rates between the two groups. Follow-up of that study, however, demonstrated that neurodevelopmental outcome at 2 years of age was not worse in the HFOV arm than in the conventionally treated infants (Truffert et al. 2007). Meta-analysis of the results of all prophylactic studies (Henderson-Smart et al. 2007) did not find a statistically significant effect overall on short-term neurological abnormality and no significant excess of ICH or PVL was noted in the HFOV arm of the largest trial to date, which only included very immature infants (Johnson et al. 2002).

During HFOV, very effective carbon dioxide elimination can be achieved. Rapid, large changes in carbon dioxide tensions can occur and are associated with changes in cerebral blood flow velocity (Kavvadia et al. 2001). In a case-control study (Dimitriou et al. 2002a), rescue HFOV was associated with worse

neurodevelopmental status at 2 years; this adverse outcome was commoner in very immature babies and could not be predicted by their initial response to HFOV.

Extracorporeal membrane oxygenation

ECMO, a form of cardiopulmonary bypass, provides a method of gas exchange in patients with respiratory failure without resorting to damaging patterns of ventilatory support and allows the lungs a chance to recover. ECMO has been used as a method of respiratory support in newborns suffering from RDS, MAS, sepsis, primary PPHN, congenital heart disease and diaphragmatic hernia. Introduction of the new techniques of respiratory support for term infants has been associated with a reduction in the number of infants being referred for ECMO (Hintz et al. 2000). A greater proportion of infants now receive HFOV, iNO and/or surfactant prior to being referred for ECMO. Delay in the institution of ECMO in infants with severe MAS, however, has been associated with longer post-ECMO ventilation and a higher mortality rate (Gill et al. 2002). Delay in referral may reflect an inappropriately pessimistic view of the survival rate of MAS infants supported by ECMO (Walker et al. 2003). Early discussion with an ECMO centre is advocated to ensure appropriate timing of referral and it has been recommended that ECMO be thought of as an extension of conventional treatment in severe MAS, rather than as a last resort (Davis and Skekerdemian 2001).

Criteria for instituting extracorporeal membrane oxygenation

These have included (Bartlett et al. 1982; Andrews et al. 1984; Loe et al. 1985; Beck et al. 1986):

- severe but reversible cardiac or pulmonary disease unresponsive to optimal ventilation and pharmacological therapy; there should be no ventilator-induced damage or chronic lung disease and the baby must have had less than 10 days of aggressive IPPV
- estimated mortality risk greater than 80%; an OI ($\text{MAP} \times \text{FiO}_2/\text{PaO}_2 \text{ postductal} \times 100$) >40 historically had been associated with 90% mortality, but in the UK ECMO trial (UK Collaborative ECMO Trial Group 1996, 1998), an OI >40 was associated with a 41% mortality rate
- birthweight >2.0 kg
- gestational age greater than 34 weeks
- no bleeding disorder
- absence of prolonged perinatal hypoxic ischaemia predicted to produce brain damage
- no chromosomal or congenital abnormality incompatible with quality of life.

Technique

Cannulation for ECMO is either venoarterial (VA) or venovenous (VV) (Andrews et al. 1983). Venous blood is usually drained from the right jugular vein; oxygen is then added and carbon dioxide removed by the membrane lung; oxygenated blood is then returned to the patient. For VA bypass, the right common carotid artery and right internal jugular vein are used. Approximately 80% cardiopulmonary bypass is achieved and the level of respiratory support can be reduced, limiting further barotrauma. In VV bypass, oxygenated blood is returned via the right femoral vein or umbilical vein and the carotid artery is spared. VV ECMO can also be undertaken through a double-lumen catheter. A disadvantage of VV ECMO is that cardiopulmonary bypass is not attained and thus the infant must have good myocardial function. There have been no

head-to-head trials comparing VA and VV ECMO, but data from the ELSO registry suggest that mortality may be lower with VV ECMO (8.5% versus 16.2%) (Gauger et al. 1995).

Total respiratory support is provided by an extracorporeal blood flow of approximately 100 ml/kg/min, increasing up to 120 ml/kg/min (Bartlett et al. 1982; Loe et al. 1985). To allow the lung to rest, during VA ECMO, inspired oxygen concentrations of 21–40% and ventilator rates of 10–20/min at pressures of 16–20 cmH₂O are used. In both VA and VV ECMO, venous blood is pumped to an oxygenator, which has blood and gas compartments separated by a semipermeable membrane, where diffusion of oxygen and carbon dioxide occurs. Oxygen transfer is controlled by the membrane's surface area, pump flow and the degree of saturation of the venous blood. Carbon dioxide elimination is adjusted by altering the flow rate. Infants are heparinised to achieve whole-blood activated clotting times (ACT) two to three times normal (an ACT of 160–200 s). Haematocrit and platelet count are maintained with transfusion of saline-washed, packed red blood cells and platelet concentrates as necessary.

When the baby starts to improve, as indicated by improving oxygenation, the ECMO circuit flow is gradually reduced to 50 ml/min. When stable vital signs, adequate urine output and acceptable arterial blood gases are achieved on this minimal flow for 4–5 hours, the ECMO cannulae are clamped, and the baby excluded from the ECMO circuit, which can be restarted if necessary.

Results

A multicentre UK trial involving 185 infants demonstrated that, compared with CMV, ECMO reduced mortality by 50% in infants with PPHN or MAS (UK Collaborative ECMO Trial Group 1996). Survival rates are highest in infants with MAS (90%), 76% in BPD infants but only 50% in CDH infants (Table 27.13).

Complications

Local vascular complications occur, including haemorrhage, vessel thrombosis and problems with wound healing. The babies can suffer from anaemia and thrombocytopenia as the result of consumption of blood products at the oxygenator's membrane surface. Mechanical problems occur in up to 20% of patients.

Sequelae

The results of anecdotal follow-up studies need to be interpreted with caution, as the infants were extremely ill prior to receiving ECMO and their original illness may be at least partially responsible

Table 27.13 Survival related to disease of the first 7647 infants reported to the Extracorporeal Life Support Organization (ELSO) registry

DIAGNOSIS	SURVIVAL RATE
Meconium aspiration syndrome	93
Severe respiratory distress syndrome	83
Persistent pulmonary hypertension of the newborn	83
Sepsis	77
Congenital diaphragmatic hernia	59
From Kanto (1994) with permission.	

for any chronic morbidity. Follow-up at 1 year of infants entered into the UK multicentre randomised trial did not demonstrate any excess of severe disability. At 4 years of age, one in four survivors had evidence of impairment with or without disability; the ECMO group had higher survival rates (Bennett et al. 2001).

There have been few studies reported on the long-term respiratory status of ECMO survivors. Short et al. (1987) found a 15% prevalence of BPD, the risk factors being culture-proven streptococcal sepsis and late placement (7–8 days of age) on ECMO. Other risk factors for BPD are lung hypoplasia and failure to respond to a trial of HFOV (Schwendeman et al. 1992). Comparison of non-randomised infants suggested that conventionally treated patients, compared with those supported by ECMO with similar illness severity, have a higher rate of BPD (Walsh-Sukys 1993). Examination at 1 year of 77 infants from the UK randomised trial demonstrated that the ECMO-treated infants had slightly better lung function, with higher inspiratory conductance and V_{\max} FRC (Beardmore et al. 2000). At 7 years, there were no significant differences in the learning problems of the two groups, but there were higher respiratory morbidity and an increased risk of behavioural problems in children in the control group (McNally et al. 2006).

Liquid ventilation

Liquid ventilation (Clark and Gollan 1966) is performed using perfluorocarbons (PFCs), which have a low surface tension (25% of that of water) and a high solubility for respiratory gases, particularly oxygen. PFCs contain carbon and fluorine bonds, which are extremely strong, making them pharmacologically and chemically inert; in addition, they are radiopaque.

Liquid ventilation may be total, in which the PFC is preoxygenated and warmed as it is circulated to fill the lungs to the expected FRC (Hirschl et al. 1995a). The PFC is then moved backwards and forwards at a relatively slow rate and high tidal volume because of the high viscosity of PFC (Hirschl et al. 1995a). Total liquid ventilation requires different circuitry from that used in current clinical practice. Partial liquid ventilation (PLV) or PFC-associated gas exchange has been used to support patients. During PLV, PFC again fills the lungs to FRC, but the patient is then gas-ventilated 'on top'. If no further PFC is given, the PFC in the lung simply evaporates away. Throughout the period of PLV, usually less than 7 days, the PFC is topped up via a side port in the ETT so that a meniscus remains visible there (Hirschl et al. 1995a; Leach et al. 1995a).

In animal models, liquid, as compared with gas, ventilation has been demonstrated to reduce ventilation-perfusion mismatch and improve compliance and oxygenation (Tütüncü et al. 1993). It also appears to be a less damaging form of respiratory support, particularly in very immature animals (Wolfson et al. 1992; Hirschl et al. 1995a). It is compatible with both NO (Wilcox et al. 1995) and surfactant (Leach et al. 1995a). Indeed, it appears to have several advantages over surfactant therapy, as it is not inactivated by proteins and has better spreading capability (Leach et al. 1995b).

Clinical studies

Experience to date is limited to small series; the majority of patients receive PLV while on ECMO. Under such circumstances, in adults (Hirschl et al. 1995b), children and neonates (Gross et al. 1995; Leach et al. 1995b; Greenspan et al. 1997), PLV has been demonstrated to improve oxygenation and compliance. PLV has also improved oxygenation in premature infants with severe respiratory failure (Leach et al. 1996). It has been suggested that PLV can

enhance pulmonary function (Pranikoff et al. 1996) and that lung growth can apparently be induced by distension of the lung with PFC in neonates with CDH (Hirschl et al. 2003). In a small randomised trial, however, no statistically significant differences in the number of ventilator-free days or survival rate were found between CDH infants supported by ECMO who did or did not additionally receive PLV (Hirschl et al. 2003).

Care of babies on ventilators

Intubation

The technique of intubating babies and the choice of tubes are described on Ch. 44. Intubating small, sick babies can be difficult; babies may become hypoxaemic, acidaemic and bradycardic during the procedure. During intubation, stress hormones are released (Lehtinen et al. 1984; Shribman et al. 1987), BP and ICP rise (Raju et al. 1980), and this, together with the blood gas changes, predisposes the neonate to GMH/IVH (Ch. 40.5) (Kelly and Finer 1984; Marshall et al. 1984; Friesen et al. 1987). For this reason, it is recommended (Kelly and Finer 1984) that infants who are electively intubated should receive premedication; effective regimes are a combination of atropine, an analgesic (such as fentanyl) and a muscle relaxant (such as mivacurium or succinylcholine) (Dempsey et al. 2006; Lemyre et al. 2009). Atropine abolishes the bradycardia and muscle relaxants attenuate the rise in ICP. In addition, use of suxamethonium, a rapidly acting muscle relaxant, shortens the duration of intubation and hence reduces the duration of hypoxaemia that commonly occurs during intubation. Suxamethonium should, however, be given with a vagolytic drug to pre-empt the potential profound bradycardia that can occur with its administration. Sedation/analgesia should also be administered with the muscle relaxant. Morphine commonly has been used, often on its own (Whyte et al. 2000), but fentanyl and alfentanil have a more rapid onset and shorter duration of action. Fentanyl can cause chest wall rigidity, but this resolves promptly with administration of suxamethonium and can be minimised by slow bolus administration.

It is important to use an appropriate-sized tube (Ch. 44). If too small a tube is used, suctioning becomes difficult. In addition, if there is a large leak around the tube, high peak inflating pressures cannot be achieved. Tube size also influences the inspiratory and expiratory resistance; the calculated mean difference in expiratory resistance between tubes of 2.5 mm and 3.5 mm internal diameter was 93 cmH₂O/l/s (Farstad and Bratlid 1991). Shortening an ETT to an appropriate length also reduces its resistance. Changing an oral ETT used for labour ward resuscitation to a nasal ETT on a routine basis is not necessary. There is no evidence that nasal tubes are superior to oral tubes for routine use (McMillan et al. 1986). Nasal ETTs can be easily fixed at the nose, which might reduce laryngeal trauma, but ulceration and excoriation of the nostrils can occur. Oral tubes are generally thought to be easier to insert, but infants may suck on an oral ETT and, at follow-up, high palatal arches, pressure-induced grooves and even clefts in the palate have been described.

Humidification

Inadequate warming and humidification of inspired gases will cool the baby and lead to dehydration of the bronchial secretions with airway plugging and obstruction of the ETT. The gas from the ventilator should reach the ETT adequately warmed and humidified. The British Standards Institution (1970) recommends that the minimal accepted humidity is 33 mgH₂O per litre inspired gas, which is 75% of that obtained during normal breathing.

Fixation

Many techniques for immobilising ETTs have been described. These include purpose-made devices such as a flange sewn to the ETT and then tied to either side of a bonnet or simply using adhesive tape stuck around the tube and then to the infant's face. It is important to use a system which minimises accidental extubation and avoids causing cosmetic deformity (Ch. 44).

Suctioning

Suctioning can cause bradycardia, hypoxia, bacteraemia and pneumothorax, and an increase in cerebral blood flow and ICP but a fall in cerebral oxygenation (Simbruner et al. 1981; Perlman and Volpe 1983; Murdoch and Darlow 1984; Tarnow-Mordi 1991; Skov et al. 1992), though these effects are less in the paralysed baby (Fanconi and Duc 1987). The technique of ETT suction must allow oxygen administration throughout the procedure, and if the baby becomes bradycardic or the tcPo_2 , continuous PaO_2 monitoring or oximetry demonstrates the oxygenation to have fallen below 6 kPa or the SpO_2 below 80%, suction should be discontinued and the infant reconnected to the ventilator.

Inserting the suction catheter until a resistance is felt (when the catheter hits the carina) should be avoided. The suction tube should only be inserted far enough to reach just beyond the tip of the ETT (Bailey et al. 1988).

Both saline and water can damage the lungs and/or the surfactant system (Lachman 1987), particularly if the fluid is not adequately warmed (John et al. 1980). If some form of lubrication is deemed essential to enable the suction catheter to pass down the ETT, the smallest amount of fluid necessary, probably 0.3–0.5 ml, should be used.

Endotracheal suctioning during the acute respiratory illness should be minimised and tailored to the need of the individual neonate. There is no evidence that suctioning is needed more often than every 12 hours in the routine care of babies ventilated for RDS (Wilson et al. 1991).

Complications of intubation

The mucosa of the larynx and trachea shows deciliation, necrosis and desquamation within hours of intubation (Joshi et al. 1972; Gau et al. 1987) and metaplastic change in the trachea occurs (Rasche and Kuhns 1972). Nevertheless, remarkably few long-term sequelae are seen. Many neonates have some hoarseness and/or mild stridor, but only in the 24–48 hours after extubation, and although tracheomegaly can occur after prolonged intubation (Bhutani et al. 1986), it seems to cause little functional problem. Serious damage to the larynx and trachea, such as granulomata or subglottic stenosis or cysts, is uncommon. These sequelae occur in babies who have had prolonged and/or repeated intubations (Sherman et al. 1986) and can be minimised by meticulous attention to ETT immobilisation and by skilled and judicious timing of extubation.

Tracheostomy

See Chapter 27 part 7.

Paralysing babies during ventilation

Administration of neuromuscular blocking agents can reduce the incidence of airleaks if given to preterm babies who are actively expiring against the ventilator (Greenough et al. 1984a). Such agents, however, do have adverse effects. In babies with active respiration, albeit out of phase with ventilator inflation, abolition of spontaneous respiratory activity is associated with a fall in PaO_2 and

a rise in Paco_2 (Runkle et al. 1984) following pancuronium or morphine administration. Lung function may deteriorate, with a fall in compliance and FRC and a rise in airways resistance, leading to a fall in oxygenation (Bhutani et al. 1988b). This deterioration in oxygenation can usually be overcome by increasing the peak inspiratory pressure by 4–6 cmH_2O immediately prior to giving the first dose of pancuronium. The use of a neuromuscular blocker results in neonates being ventilated for a longer period of time and developing oedema (Greenough et al. 1987), although this is not associated with a fall in plasma volume (Buckner et al. 1991). Prolonged use has been suggested to cause contractures or muscle atrophy (Sinha and Levene 1984; Rutledge et al. 1986), but this can be avoided by appropriate passive physiotherapy.

Paralysis should also be considered for:

- the mature term baby with MAS, PPHN or GBS sepsis who is chronically restless, hypoxic and impossible to maintain in synchrony with the ventilator, despite sedation and rate and inspiratory time manipulation; infants with CDH should all be paralysed from birth (Ch. 27.6)
- any neonate, irrespective of gestation, who shows the 'active expiratory reflex' pattern and in whom this is not abolished by synchronous ventilation and sedation
- any neonate who develops severe PIE and infants who remain restless despite sedation following drainage of a pneumothorax.

Pancuronium is the most commonly used drug in this situation, given at intervals to suppress all respiratory activity, as it has fewer side-effects than curare. Strict attention to fluid balance is mandatory, as fluid retention during paralysis is common. The excretion of pancuronium in the neonate with kidney and liver problems is variable and this agent interacts with other drugs, in particular the aminoglycosides (Nugent et al. 1979); in consequence, very high plasma levels and prolonged paralysis may occur with infusions of the drug. This may worsen pulmonary mechanics (Bhutani et al. 1988). Hence, infusions should be avoided and the drug given by boluses as required, although this does not necessarily avoid all the side-effects. Other neuromuscular blocking agents include vecuronium, atracurium and cisatracurium, the last is a potent isomer of atracurium, but is devoid of histamine-releasing properties in clinical doses and has no breakdown neuromuscular products associated with neuromuscular blocking activity (Reich et al. 2004). In contrast, vecuronium has an active metabolite and is dependent on hepatobiliary and renal excretion (Reich et al. 2004). In neonates and infants, there is a markedly shorter recovery of neuromuscular transmission after cisatracurium than after vecuronium (Reich et al. 2004). Variation in sensitivity of the neuromuscular junction in neonates also means that the initial dose of vecuronium given should be small (10–20 μg) and, as the duration of action and recovery time is longer in babies, maintenance doses should also be low. If 'paralysis' is required for a prolonged period, infants become oedematous, and this is only partially responsive to fluid restriction. It is important to restrict use of neuromuscular blocking agents, as a high daily dose in association with loop diuretics has been associated with an increased risk of sensorineural hearing loss (Robertson et al. 2006).

Analgesia/sedation (Ch. 25)

Physiotherapy in ventilated neonates

Meta-analysis of the results of 13 studies, however, demonstrated no significant differences in long-term outcomes amongst

ventilated infants who were or were not given opioids, but those receiving morphine took significantly longer to reach full enteral feeding (Bellu et al. 2010). Amongst infants supported by CPAP, a single low dose of morphine (0.01 mg/kg) was associated with significant reductions in heart and respiratory rates; although the overall incidence of apnoea did not differ compared with the pre-morphine period, six infants experienced delayed apnoea (Enders et al. 2008). Remifentanyl is an ultra-short-acting opioid with a half-life of 10–35 minutes. In a randomised trial (Silva et al. 2008), the length of time to awaken and extubate was 18 and 12 times longer, respectively, with morphine than with remifentanyl. It has been shown to provide adequate analgesia in ventilated infants at an infusion rate of 0.094 µg/kg/min (Giannantonio et al. 2009) and has been used as an induction agent for the INSURE procedure (Welzing et al. 2009).

Physiotherapy in ventilated neonates

Problems with retained sticky secretions or ETT blockage are rare in the first 3–4 days of IPPV if adequate humidification of the ventilator gases is undertaken. Chest physiotherapy on ventilated babies with RDS may cause serious hypoxia and release of stress hormones (Griesen et al. 1985); physiotherapy is, therefore, not warranted as a routine (Fox et al. 1978; Simbruner et al. 1981; Wilson et al. 1991). Frequent endotracheal suction and/or regular chest physiotherapy may be needed, however, in babies with:

- pneumonia and increased secretions (Ch. 39.2)
- meconium aspiration (p. 501)
- MPH (p. 509)
- bronchorrhoea as BPD develops (p. 552).

Posture

The position of ventilated neonates should be changed 2–3-hourly from the back to the right and then the left side, to aid movement of airway secretions. The prone position (except in babies with UACs) with the baby's head turned to one side should also be used, since this will facilitate drainage of secretions and improvement of blood gases (Wagaman et al. 1979; Dimitriou et al. 1996). The neonate with severe PIE should lie on the affected side, since this hastens the disappearance of interstitial gas.

Deterioration on intermittent positive pressure ventilation

Not all babies who are stable on IPPV remain so: their condition may, and often does, worsen, and this can be a sudden collapse or a gradual deterioration.

Sudden collapse

Sudden spontaneous episodes of hypoxaemia are not uncommon in ventilated preterm babies. These may be due to episodes of active exhalation (Bolivar et al. 1995) and usually respond to short-term increases in F_{iO_2} or pressure; infants who continue to expire actively should be paralysed. More prolonged deterioration is usually due to one of three things: a blocked or displaced ETT, an acute airleak, usually a pneumothorax, or the sudden development of a large GMH/IVH. If the third possibility is not present, prompt and efficient management of the other two is essential to prevent it developing. It is important to establish that the ETT is in situ and patent by observing whether there is adequate chest wall excursion and auscultating the chest. A capnometer, which detects exhaled carbon, may facilitate detection of extubation (Sutherland and Quinn 1993) by demonstrating the absence of intermittent changes in

carbon dioxide in time with ventilation. The development of a pneumothorax, by either transillumination or CXR, must then be excluded; if the infant's condition is critical, emergency chest aspiration should be considered (Ch. 44).

Gradual deterioration

The respiratory condition of infants with RDS who have not received surfactant will worsen over the first 24–48 hours. Other reasons for a ventilated baby to deteriorate gradually include the development of pneumonia, a GMH/IVH, anaemia, hypotension, an airleak or pulmonary oedema. In addition, partial blockage of the ETT and progression to BPD will be associated with worsening blood gases.

The severely hypoxic neonate

Hypoxia with normocapnia or hypocapnia

In the absence of severe lung disease and in infants with mild RDS or MAS, the blood gas abnormalities should be managed as outlined for PPHN. In infants with severe lung disease who remain severely hypoxic (P_{aO_2} , 5 kPa in 95% oxygen) despite treatment of coexisting problems, the options are to increase the level of ventilatory support, use vasodilator drugs (p. 498) and, in an infant born at or near term, consider use of ECMO (pp. 525–526). The MAP should be increased because, by causing an improvement in lung volume, this can increase oxygenation. MAP can be increased by elevating either the peak inflating pressure or PEEP level or by prolonging the inflation time (with a reversed I:E ratio); the most effective manoeuvre, however, is to increase the PEEP level. Infants who are actively expiring against the ventilator and/or are receiving a peak inflating pressure >25 cmH₂O should be paralysed. If these manoeuvres fail and the infant has an adequate BP (Appendix 4), pulmonary vasodilator drugs (p. 498) should be given.

It is essential to check that the baby has not been overventilated to such an extent that the MAP is compromising pulmonary artery perfusion and causing iatrogenic PPHN. The diagnostic clues are a low P_{aO_2} and a very low P_{aCO_2} , often less than 3–3.5 kPa (23–26 mmHg), a raised pH (<7.45–7.50) and a CXR showing dark overexpanded lungs. A similar situation may be seen with inadvertent PEEP in older babies with BPD and an increased airways resistance; reducing the ventilator rate and hence increasing the expiratory time will dramatically improve ventilation (Stenson et al. 1995).

Profound hypoxaemia with carbon dioxide retention

If severe hypoxaemia is combined with hypercapnia, particularly if this is 7–8 kPa (52–60 mmHg), and technical problems with the ventilator circuit and tube have been excluded, the ventilator pressure and/or rate should be increased. If very high inflation pressures (35 cmH₂O) are being used, in a neonate who is clinically stable with an acceptable BP, less than perfect blood gases can be tolerated, provided that the P_{aO_2} is 5.5–6.0 kPa (41–45 mmHg), the P_{aCO_2} 8 kPa (60 mmHg) and the pH 7.25.

Weaning

It is important to wean an infant from mechanical ventilation and extubate as soon as possible, as complications of IPPV such as infection, BPD and airleak are related to the duration of IPPV. There are, however, dangers in trying to get a baby off IPPV too quickly, particularly in the very preterm baby in whom too rapid a weaning process may result in a recurrence of severe atelectasis and the need for more intensive ventilator support than before.

Once satisfactory blood gases have been achieved (P_{aO_2} 8–12 kPa (60–90 mmHg), P_{aCO_2} >5.5–6.5 kPa (40–50 mmHg), pH >7.25) and the baby has been stable at these levels for 6 hours, weaning should begin. During weaning, the most damaging modality of ventilation should be reduced first, i.e. the peak inspiratory pressure, as this is a factor in the aetiology of pneumothorax and BPD (Ch. 27.3). After reducing the peak pressures down to 25 cmH₂O and the inspired oxygen concentration to less than 60%, if the P_{aO_2} is >8–9 kPa (60–70 mmHg) and the P_{aCO_2} is well controlled or if there is a respiratory alkalaemia, the oxygen concentration and peak pressures can then be reduced simultaneously. In general, the settings should be reduced in small increments: 5–10% for oxygen and 2–3 cmH₂O for peak inspiratory pressure; too rapid or too large changes can result in the baby becoming hypercapnic and/or hypoxic. After each change, it is important to check the blood gases within 30–60 minutes to ensure that they are still satisfactory. If the blood gases are acceptable (P_{aO_2} >8 kPa (60 mmHg), pH >7.25) and the baby is breathing spontaneously, the settings should be reduced every 4–6 hours.

Pancuronium should not be discontinued until problems due to airleaks (severe PIE or pneumothorax) have been controlled and the ventilator settings have been reduced to 22–25 cmH₂O and 50–60% oxygen.

Once the baby is making spontaneous respiratory efforts and the peak pressures have been reduced to 14–18/3 cmH₂O (depending on the size of the baby), the inflation time should be reduced to 0.3–0.4 seconds. The infant should be transferred to ACV and the inflating pressures reduced still further depending on the size of the infant, before considering extubation. This approach has been shown to shorten the duration of weaning significantly (Chan and Greenough 1993a). ACV rather than sIMV is preferred as reducing the ventilator rate below 20/min, regardless of whether a patient-triggered mode is used, increases the work of breathing (Roze et al. 1997). Other triggered modes, for example PSV with or without volume guarantee (p. 522), can be used to wean babies; whether these modes are more effective than ACV requires investigation in appropriately designed randomised trials.

Once the neonate is in 30% oxygen and the peak inflating pressures reduced to 10–16 cmH₂O, the baby will usually be ready to extubate. Delay in extubation following 36 hours of optimised mechanical ventilation does not improve the rate of successful extubation (Danan et al. 2008). Some prefer to extubate babies only after they have been able to maintain their blood gases on endotracheal CPAP (etCPAP). The period on etCPAP should, however, be limited to an hour or less (Kim and Boutwell 1987), as breathing through a narrow ETT increases the work of breathing (p. 457), so the baby can tire easily. Indeed, in randomised trials, direct extubation from a low IMV rate rather than after a period of etCPAP was associated with an increased chance of successful extubation (Davis and Henderson-Smart 2001).

Infants with a birthweight less than 1.0 kg should be extubated on to nCPAP rather than directly into supplementary oxygen delivered into a headbox. Randomised trials have demonstrated that use of nCPAP postextubation reduces the need for increased respiratory support (Dimitriou et al. 2000). If nCPAP is used, after 24–48 hours the baby should then be nursed in a headbox in the same inspired oxygen concentration, restarting nCPAP if the baby develops apnoeas or shows signs of increasing respiratory distress. Time-cycling babies on and off CPAP, with increasingly longer periods off CPAP on successive days if tolerated, is not advantageous and indeed prolongs the duration of CPAP, compared with reducing the CPAP pressures (Soe 2007).

In babies >1.50 kg birthweight, weaning can often be rapid, over a period of 12–24 hours, with no need for prolonged periods on

nCPAP. Conversely, in neonates <1.00 kg birthweight, the later stages of weaning may take weeks (see below). Infants older than 1 week may benefit from extubation on to higher levels of CPAP than preterm infants less than 1 week old (6 rather than 3 cmH₂O) (Chan and Greenough 1993a).

In babies <1.5 kg and <32 weeks of gestational age, methylxanthines should be administered at least 12 hours prior to extubation. In prospective randomised controlled trials, administration of methylxanthines has been demonstrated to reduce the failure in extubation in preterm infants within 1 week of age (Henderson-Smart and Davis 2003). Theophylline, however, has side-effects, including tachycardia, vomiting, diuresis and hyperglycaemia; these are dose-related, hence it is important to monitor levels carefully. Theophylline also increases energy expenditure and augments carbohydrate utilisation, which could be detrimental to growth (Carnielli et al. 2000). A further disadvantage is that theophylline has to be given three times a day. Caffeine, then, is the weaning agent of choice, as it is administered once daily, has a lower toxicity level and fewer side-effects and in a randomised trial (Sims et al. 1989) was demonstrated to be equally effective as theophylline. Doxapram has been used in infants who appear resistant to methylxanthines, but even in low dose may cause elevation of BP and result in high plasma levels of doxapram (Huon et al. 1998); thus, we do not recommend its use.

Weaning problems

After any step in weaning, the baby may deteriorate or the blood gases at the new setting may be unacceptable. One finding which is common in VLBW neonates and which suggests that the weaning procedure is not progressing smoothly is the development over 6–12 hours of a metabolic acidaemia, a sign that the work of breathing at the new ventilator setting is excessive. In this situation, after ensuring that the baby has not suffered some unrelated adverse event such as a blocked ETT or a pneumothorax, all that is usually required is to revert to the previous ventilator setting. In some babies, however, following the deterioration, much more vigorous ventilation may be necessary for 24–48 hours before the weaning process can once more be resumed.

Extubation

Extubation carries the risk of severe hypoxia leading to GMH/IVH, inhalation of gastric contents and the need for reintubation, with a possibility of laryngeal trauma. It is essential, therefore, only to attempt extubation with the baby in the best possible condition, including normal electrolytes, a haemoglobin >13 g/dl and normal acid-base status. Feeding should be discontinued 6–12 hours before extubation and not restarted for a further 12 hours, so that the risks of regurgitation and inhalation of milk are reduced to a minimum.

After extubation, the neonate often has considerable difficulty clearing secretions as airway ciliary function has been compromised by the damage caused by the ETT. The inspired oxygen must, therefore, be humidified and warmed. No clear benefit has been demonstrated in routine, periextubation active chest physiotherapy (Flenady and Gray 2002; Hough et al. 2008) and thus physiotherapy and suction should be adapted on the basis of clinical findings or the CXR.

Prediction of successful extubation

A variety of univariate indices have been assessed in an attempt to improve prediction of extubation success, including minute ventilation (Wilson et al. 1998; Vento et al. 2004; Kamlin et al. 2006) and compliance (Kavvadia et al. 2000a; Dimitriou et al. 2002b) and

resistance (Veness-Meeham et al. 1990) of the respiratory system, but none has been found to be a consistently reliable predictor. In one study (Kavvadia et al. 2000a), a low lung volume (FRC <26 ml/kg) was more predictive of extubation failure (need for reintubation) than compliance, tidal volume or respiratory rate results, but only if the lung volumes post- rather than pre-extubation were considered. In addition, although respiratory muscle strength, as measured by the maximal inspiratory pressure ($P_{i_{max}}$), has been reported to differ significantly according to extubation outcome (Shoults et al. 1979; Belani et al. 1980), in another study (Kamlin et al. 2006) the significant difference in $P_{i_{max}}$ results according to extubation outcome disappeared when the $P_{i_{max}}$ results were corrected for weight. Extubation success depends on the adequacy of respiratory drive, the capacity of the respiratory muscles and the load imposed upon them and hence composite indices are likely to be more predictive than univariate indices. The tension time index of the diaphragm (TT_{di}) (Bellemare and Grassino 1982a, b) is a measure of the load on and the capacity of the diaphragm; it requires measurement of intrathoracic and intra-abdominal pressure to obtain transdiaphragmatic pressure. A non-invasive tension time index (TT_{mus}) based on airway pressure measurements, however, has been developed and was 100% sensitive and specific in predicting extubation failure in children (Harikumar et al. 2009). A TT_{di} of >0.15 and a TT_{mus} of >0.18 were 100% sensitive and 100% specific in predicting extubation failure, but only 20 infants were included in the study (Currie et al. 2010).

Extubation problems

Stridor

Minor degrees of stridor are not uncommon and usually only last for an hour or two or at most 24 hours. If persistent, the infant may benefit from high-pressure nasopharyngeal CPAP, using pressures up to 6–8 to 10 cmH₂O; whether or not this will work can only be assessed on a trial-and-error basis. Nebulised adrenaline (epinephrine) can also be administered. If the stridor is marked and unresponsive with severe respiratory distress and there is progressive deterioration of the blood gases, there is no alternative but to reintubate. In such patients, the ETT should be left in place with the baby on minimal ventilation for at least 2–3 days before a further attempt at extubation is made after pretreating the baby with dexamethasone (0.5 mg/kg) for 24 hours and continuing the drug for 24–48 hours after extubation (Corbet et al. 1991). The management of the baby in whom this does not work and in whom some more serious laryngeal damage has occurred is outlined on Chapter 27 part 7.

Lobar collapse

Despite careful physiotherapy and suction postextubation, up to 20% of neonates develop collapse/consolidation of one lung or just one lobe, particularly the right upper, because of plugging of the bronchi with secretions (Wyman and Kuhns 1977) (Fig. 27.42). This complication seems to be more common after nasal intubation (Spitzer and Fox 1982). It may cause such severe

Fig. 27.42 Atelectasis of the right lung. The infant required reintubation and ventilation prior to the chest radiograph because of poor blood gases postextubation.

deterioration that reintubation and IPPV are necessary, but other infants may be virtually asymptomatic. Milder cases can be treated by vigorous physiotherapy. Occasionally it is worth sucking out the airway of more severely affected neonates under direct vision at laryngoscopy. By turning the head away from the affected lung, the suction catheter can usually be directed into the appropriate main stem bronchus.

In order to detect areas of asymptomatic collapse, particularly in the right upper lobe, before they progress to total lung collapse, neonates should be X-rayed within 24 hours of extubation and whenever there is any deterioration in their clinical condition or blood gases. The development of significant intercostal/subcostal retractions and an increase in the inspired oxygen concentration of at least 7% has been suggested to be a sensitive indicator of radiological deterioration (Fok et al. 1998).

Recurrent failure to wean or extubate

Repeated unsuccessful attempts to extubate a neonate over a period of a week is usually only a problem in ELBW neonates whose weight is not increasing and in whom the repeated episodes of extubation and deterioration make adequate nutrition even more difficult to achieve. Rarely it is due to laryngeal damage. Poor lung function is not usually responsible (Veness-Meeham et al. 1990). Affected infants should be reintubated and restarted on IPPV at the minimal settings necessary to achieve normal blood gases and kept there until they are in a better condition and gaining weight consistently. Repeated failure to wean a neonate off IPPV is very suggestive of a neurological problem, secondary to either GMH/IVH or some primary muscular or neurological disorder, including, particularly in term babies, the congenital hypoventilation syndrome (Ondine's curse).

Part 3: Chronic lung disease

Anne Greenough Anthony D Milner

Chronic lung disease (CLD) has been used as the diagnosis for all babies who are oxygen-dependent beyond 28 days of age with an abnormal chest X-ray (CXR) appearance. On the basis of the clinical course and/or CXR appearance some identify distinct forms of CLD, such as Wilson–Mikity syndrome. Nowadays, following the consensus at a US National Institutes of Health (NIH)-sponsored workshop, the term bronchopulmonary dysplasia (BPD) rather than CLD is used as the ‘umbrella’ term for all oxygen-dependent babies, as it better distinguishes the neonatal lung process from the CLDs seen in later life (Jobe and Bancalari 2001). As a consequence, the term BPD as defined in the NIH consensus (Jobe and Bancalari 2001) will be used throughout this chapter, except to describe the Wilson–Mikity syndrome.

Bronchopulmonary dysplasia

The four stages of BPD were originally based on a sequence of CXR changes (Northway et al. 1967). In the present population of babies, particularly those born at very early gestations, those stages do not occur consistently. Indeed, babies may develop BPD even though they had mild or absent initial respiratory distress (Rojas et al. 1995). At an NIH-sponsored workshop, it was recommended that babies be considered to have BPD if they had been oxygen-dependent for at least 28 days and then classified as suffering from mild, moderate or severe BPD according to their respiratory support requirement at a later date. It was recommended that babies born at less than 32 weeks of gestational age be assessed at 36 weeks’ postmenstrual age (PMA) or at discharge home, whichever came first. They were diagnosed as having mild BPD if at that time they

were breathing air, moderate BPD if they required less than 30% supplementary oxygen, and severe BPD if they needed more than 30% oxygen and/or positive-pressure ventilation or nasal continuous positive airway pressure (CPAP). It was recommended that infants born at 32 weeks of gestation or greater be assessed at 56 days’ postnatal age or discharge home, whichever came first, and at that time the severity of their BPD be graded, as for the more immature babies, according to their respiratory support requirement (Jobe and Bancalari 2001). The consensus BPD definition has been shown to identify a spectrum of risk for adverse pulmonary and neurodevelopmental outcomes in early infancy more accurately than other definitions (Ehrenkranz et al. 2005).

Incidence

The incidence of BPD in very-low-birthweight (VLBW) babies has been reported to vary from 15% to 50%. This is partially explained by differences in the proportions of very immature babies in the populations considered, as the incidence of BPD is inversely related to gestational age. In some centres, the number of BPD infants is increasing. A survey of a geographically defined population in the Trent Health Region demonstrated that the incidence of BPD had increased from 25% in 1987 to 42% in 1997 when defined as oxygen dependency at 28 days and from 11% to 29% over the same time period when defined as oxygen dependency at 36 weeks’ PMA. It was noted that this increase was associated with a greater number of babies of less than 33 weeks’ gestational age being admitted to the neonatal units (Manktelow et al. 2001). The increase in the number of cases of BPD has been suggested to be due to the

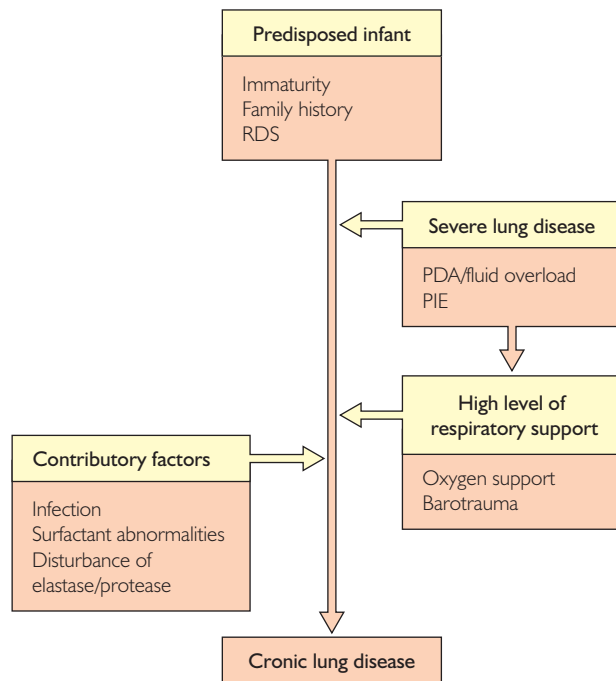

Fig. 27.43 Aetiological associations of bronchopulmonary dysplasia. PDA, patent ductus arteriosus; PIE, pulmonary interstitial emphysema; RDS, respiratory distress syndrome. (Redrawn from Greenough *et al.*)

improved survival of very immature babies. Another factor that influences the incidence of BPD is the criterion for the use of supplementary oxygen: the higher the oxygen saturation level to be maintained, the greater the number of infants who will require supplementary oxygen. A survey of members of the Vermont Oxford Network highlighted that pulse oximetry saturation thresholds varied from 84% to 96%, with only 41% of the respondents using the same criteria (90%) (Ellsbury *et al.* 2002). It is recommended that, at least at 36 weeks' PMA, a room air oxygen saturation test is undertaken to determine if the infant requires supplementary oxygen to maintain saturation level at 90% or above (Walsh *et al.* 2004).

Aetiology (Fig. 27.43)

BPD commonly occurs in prematurely born babies who have had respiratory distress syndrome (RDS), but also occurs in immature infants who had no initial lung disease (Rojas *et al.* 1995). Babies born at term may also develop BPD (Barnes *et al.* 1969; Rhodes *et al.* 1975), particularly if they suffer severe initial lung disease, as evidenced by a requirement for extracorporeal membrane oxygenation (Kornhauser *et al.* 1994).

Many factors increase the risk of BPD development, including those listed below.

Immaturity

There is an inverse relationship between the incidence of BPD and gestational age. Agents prolonging pregnancy, however, may not reduce BPD. Antenatal administration of indometacin significantly prolonged the gestation of women with threatened preterm labour between 24 and 34 weeks. There was, however, an increased BPD rate, particularly in babies delivering within 120 hours of their mothers starting treatment (Eronen *et al.* 1994). Administration of

indometacin may have delayed development of lamellar bodies and surfactant components (Eronen *et al.* 1994).

Oxygen toxicity

Northway *et al.* (1967) originally ascribed BPD to oxygen toxicity, as the chronic phase was invariably associated with high oxygen concentrations for more than 150 hours. Prolonged exposure to high oxygen concentrations has complex biochemical, microscopic and gross anatomical effects on lung tissues (Bonikos *et al.* 1976; Crapo *et al.* 1978; Escobedo and Gonzalez 1982). Oxygen toxicity is caused by the increased production of cytotoxic oxygen free radicals, which overwhelm the antioxidant defences. Prematurely born infants are particularly vulnerable; they have incomplete development of their pulmonary antioxidant enzyme systems and low levels of antioxidants such as vitamins C and E.

Baro- or volutrauma

BPD was first reported in babies who received oxygen concentrations of less than 60%, when used in association with CPAP (Tooley 1979) or mechanical ventilation (Ballard *et al.* 1992). Intermittent positive-pressure ventilation seemed particularly damaging if peak inflating pressures above 35 cmH₂O were used (Berg *et al.* 1975; Taghizadeh and Reynolds 1976). Baro- or volutrauma was further incriminated by the demonstration of an inverse relationship between hypocarbia and BPD development (Kraybill *et al.* 1989; Garland *et al.* 1995). Infants with P_{aCO_2} levels <29 mmHg before surfactant therapy had an odds ratio of 5.6 for developing BPD as compared with babies who had a P_{aCO_2} of at least 40 mmHg (Garland *et al.* 1995). Volutrauma may occur at resuscitation if rapid lung expansion is attempted. Prematurely born lambs given six manual inflations of 35–40 ml/kg, compared with those not 'bagged' at birth, had poorer lung function at 4 hours of age, as indicated by lower inspiratory capacities (Bjorklund *et al.* 1997). Use of high tidal volumes at resuscitation can also compromise the response to surfactant therapy in preterm lambs (Wada *et al.* 1997).

Patent ductus arteriosus and fluid balance

The association of patent ductus arteriosus (PDA) and an increased risk of BPD has frequently been reported. The effect is potentiated by infection, particularly if temporally related (Gonzalez *et al.* 1996). Prophylactic use of low-dose indometacin, initiated in the first 24 hours after birth, however, did not significantly reduce the incidence of BPD, even though it decreased the incidence of symptomatic PDA (Couser *et al.* 1996; Fowlie 1996). Fluid overload may explain the association of PDA and BPD, as it causes congestive heart failure and hence deterioration in lung function. Multivariate assessment of the traditional risk factors for BPD in babies with birthweight less than 1200 g also highlighted that oxygen dependency was associated with high fluid intake, as well as with PDA and high ventilator pressures at 96 hours (Palta *et al.* 1991). Amongst extremely-low-birthweight (ELBW) infants, daily fluid intakes were higher and there was weight loss delay in those who developed BPD or died (Oh *et al.* 2005).

Airleak

Pulmonary interstitial emphysema has been associated with a high incidence of BPD (Cochran *et al.* 1994). Respiratory function is compromised by air dissection into false air spaces, which creates a large dead space for ventilation; these spaces then increase in size with time and compress lung tissue.

Infection

Antenatal

It has been suggested that chorioamnionitis may predispose to BPD. In one series (Watterberg et al. 1996), 63% of babies with BPD but 21% of babies without BPD had exposure to chorioamnionitis. The chorioamnionitis group, however, were of significantly lower gestational age and the data were not adjusted for that difference. In a case-control study (van Marter et al. 2002), histological chorioamnionitis was only associated with an increased risk of BPD if the infant subsequently developed postnatal infection or required mechanical ventilation for longer than 7 days. An increased incidence of BPD associated with chorioamnionitis has been reported in only six of 18 subsequent studies (Been and Zimmerman 2009); gestational age adjustment was performed in only one of those studies. In the remaining studies, multivariate adjustment generally showed no difference in BPD risk (Been and Zimmerman 2009). It has been suggested that the inability of many later studies to demonstrate an increased risk of BPD following chorioamnionitis may be attributed to the increased use of antenatal steroids (Been and Zimmerman 2009). In a study of 120 prematurely born infants, 90% of whom had been exposed to antenatal steroids, no excess of BPD was demonstrated in infants exposed to chorioamnionitis, nor were there any differences in lung function at follow-up between those with or without chorioamnionitis exposure (Prendergast et al. 2010).

Postnatal

BPD is twice as common in babies who develop postnatal infection with cytomegalovirus than in non-infected babies (Sawyer et al. 1987). Review of 17 studies demonstrated that the relative risk for BPD development in babies colonised with *Ureaplasma urealyticum* was 1.72 (95% confidence interval 1.5–1.96) (Wang et al. 1995). The effect may be greatest in babies with a birthweight less than 1250 g (Wang et al. 1993) and in those who did not receive surfactant (Wang et al. 1995). Only those with persistent colonisation (which accounted for 45% of *U. urealyticum*-positive VLBW babies in one series), however, might be at increased risk of BPD (Castro-Alcaraz et al. 2002).

Surfactant abnormalities

BPD has been associated with persisting surfactant abnormalities (Obladen 1988). The lecithin:sphingomyelin ratio increased slowly in BPD babies (Hallman et al. 1987) and phosphatidylglycerol was noted to appear several months later in BPD babies who died rather than survived. Proliferative changes in BPD may reduce the number of type II cells, explaining the above findings. Abnormalities related to surfactant proteins, particularly SP-A, have also been associated with BPD (Strayer et al. 1986). Deficiency of SP-A mRNA expression persisted following RDS in a model of chronic lung injury (Coalson et al. 1995). SP-A is important in blocking the surfactant-inactivating effects of serum proteins during oedema formation (p. 460).

Chronic aspiration

The concentration of pepsin has been reported to be increased in the tracheal aspirates of ventilated preterm infants who developed BPD or died before 36 weeks PMA (Farhath et al. 2008). Those results (Farhath et al. 2008) suggest that chronic aspiration of gastric contents may contribute to the pathogenesis of BPD.

Predisposition to bronchopulmonary dysplasia

The role of a family history of asthma is controversial (Nickerson and Taussig 1980; Chan et al. 1988). Babies unable to secrete adequate amounts of cortisol in settings of increased stress injury may be at risk of continuing lung injury. Low cord and first-day serum cortisol and dehydroepiandrosterone sulphate concentrations were associated with death or BPD (Nykanen et al. 2007). Similarly, at the end of the first week, babies who subsequently developed BPD had significantly lower cortisol secretion in response to adrenocorticotrophic hormone than babies who recovered without BPD (Watterberg and Scott 1995).

Genetic predisposition

Twin studies have shown that the BPD status of one twin, even after correcting for contributing factors, is a highly significant predictor of BPD in the second twin (Bhandari and Gruen 2006). Variations in candidate genes have been interrogated in a variety of sample sizes and positive associations tend to come from the smaller samples, only to be abolished in larger follow-up studies (Bhandari and Gruen 2006).

Clinical presentation

The majority of babies with BPD are born very prematurely and at 2–3 months of age remain dyspnoeic and require oxygen supplementation; some will still be ventilator-dependent. Others may have had minimal or no initial respiratory distress, but then deteriorate and become chronically oxygen-dependent; in one series (Streubel et al. 2008), 15% of ELBW infants followed this atypical pattern. A minority who have severe BPD are oedematous and have signs of right heart failure. In addition, they have chest wall retractions and other abnormalities related to a chronic increased work of breathing, such as a Harrison's sulcus. Those patients, despite increasing postnatal age, frequently fail to thrive and are at high risk of deterioration related to recurrent respiratory infections. Cor pulmonale develops in those who are chronically hypoxaemic. Copious endotracheal secretions, persistent atelectasis, lobar hyperinflation, aspiration and abnormalities of the trachea and/or bronchus are common. Bronchoscopy can reveal tracheomalacia and/or bronchomalacia. Large airway collapse can be seen on the CXR as thinning or tapering of the airways, or demonstrated by cine-computed tomography (cine-CT) (Manktelow et al. 2001). Tracheo- and bronchomalacia usually improve as the infant grows, but in severe cases surgery may be necessary. Increasing oxygen requirements, hypoxic and hypercapnic episodes in association with radiological changes of fixed lobar emphysema or recurrent atelectasis may be associated with tracheobronchial stenosis. In some affected patients, endoscopy and balloon dilation may be successful (Betremieux et al. 1995). Extubation may be complicated by inspiratory stridor secondary to tracheal scarring (Ch. 27.7).

Feeding difficulties and aspiration are common, owing to bulbar dysfunction or gastro-oesophageal reflux. They may suckle with weak pressures to maintain breathing during feeding (Mizuno et al. 2007). Parenteral nutrition may be needed, although excessive infusions of lipid solutions have been implicated in increasing the risk of BPD (Cooke 1991; Sosenko et al. 1993). Growth failure is common. Osteopenia occurs in infants with BPD and fractures can occur owing to severe metabolic bone disease in BPD babies (Fig. 27.44).

Fig. 27.44 Chest radiograph of baby with bronchopulmonary dysplasia and rib fractures due to metabolic bone disease.

Fig. 27.45 Chest X-ray of an infant with bronchopulmonary dysplasia and a patent ductus arteriosus. Note the widespread lung changes.

Imaging

Northway et al. (1967) described four distinct radiographic appearances:

- stage 1: radiographically indistinguishable from severe RDS (1–3 days)
- stage 2: marked radiopacity of the lungs (4–10 days)
- stage 3: clearing of the radiopacity into a cystic, bubbly pattern (10–20 days) (Fig. 27.45)
- stage 4: hyperexpansion, streaks of abnormal density and areas of emphysema with variable cardiomegaly (from 1 month) (Fig. 27.46).

Fig. 27.46 Late stage 4 bronchopulmonary dysplasia with gross cystic overexpansion with compression of the mediastinum.

A variety of scoring systems to quantify the CXR appearance abnormalities have been developed. One system scored the volume of the lungs, the degree of hyperinflation and the presence and severity of interstitial changes and cysts (Yüksel et al. 1991a). Using that scoring system, it was possible to predict from the appearance of the CXR at 1 month the most severe lung function abnormalities at 6 months of age (Yüksel et al. 1991a). It was noted that the babies with the highest CXR scores and lung function abnormalities were those who had cystic elements and/or interstitial changes. As a consequence, a simplified CXR score was subsequently developed, in which only the lung volume and the presence of interstitial shadows and cysts were scored (Greenough et al. 1999). The CXR appearance so assessed differed significantly between babies who were and were not oxygen-dependent at 36 weeks' PMA (Greenough et al. 2000) and those who were and were not symptomatic in the first 6 months (Thomas et al. 2003a).

In older babies with BPD, CT scans, rather than CXR, give more detailed information. Common findings on CT scan of such patients are multifocal areas of hyperaeration, linear and triangular subpleural opacities, but not bronchiectasis (Oppenheim et al. 1994). At a median age of 19 years (Wong et al. 2008), 85% of survivors of BPD had emphysema on CT examination. High-resolution CT examination may also be helpful in predicting outcome in infancy; using a scoring system for hyperexpansion, emphysema and fibrosis/interstitial abnormalities in BPD infants at approximately term those discharged home on oxygen had significantly higher scores (Ochiai et al. 2008).

Pathology

In babies who develop 'traditional' BPD, there is progression from the initial exudative stage of diffuse alveolar damage in RDS to a regenerative and fibroproliferative reparative stage. This can be divided into three phases: an early reparative stage, a subacute proliferative stage and a chronic fibroproliferative stage (Askin 1991). In early BPD, the lungs have a grossly abnormal appearance, being firm, heavy and darker than normal; the surface is irregular, with emphysematous areas alternating with areas of collapse.

Histological examination demonstrates areas of emphysema, which may coalesce into larger cystic areas, surrounded by areas of atelectasis. Florid obliterative bronchiolitis occurs, particularly if high peak inflating pressures have been used (Taghizadeh and Reynolds 1976), and results in occlusion of the airway lumen and distal pulmonary collapse. In older babies, airway injury is marked by smooth-muscle hypertrophy, squamous metaplasia of the respiratory epithelium and glandular hyperplasia (Margraf et al. 1991) and fibrosis alternating with areas of emphysema. Hypertrophy of the pulmonary arterial smooth muscle in the media and adventitial fibrous tissue is increased (Hislop and Haworth 1990). Later, normal conducting bronchi may be found, with marked uniform expansion of distal air spaces with little or no interstitial fibrosis. In long-standing, healed BPD, seen in babies aged between 2 and 40 months, there is alveolar septal fibrosis, cardiomegaly and evidence of pulmonary hypertensive vascular disease (Stocker 1986).

The pathology of BPD is now very heterogeneous, influenced by the age at death and severity of the initial illness, and can include a combination of airway, interstitial and blood vessel abnormalities (van Lierde et al. 1991). Babies with a predominantly bronchiolar pattern rather than interstitial damage usually have had more severe acute lung disease, required a greater degree of ventilatory support and died at a younger age (van Lierde et al. 1991). There are few reports describing the pathology of 'new' BPD: they highlight less interstitial fibrosis but an arrest in acinar development resulting in fewer, larger and simplified alveolar structures, a dysmorphic capillary configuration and variable interstitial cellularity and/or fibroproliferation (Husain et al. 1998; Coalson 2006). As a consequence, it has been proposed that the 'new' BPD is not primarily the injury/repair paradigm of traditional BPD, but rather a maldevelopment sequence resulting from interference/interruption of normal developmental signalling for terminal maturation and alveolarisation of the lungs of very preterm infants (Jobe and Ikegami 1998).

Pathophysiology

Alveolar hypoplasia and dysmorphic changes in the lung vasculature are consistent findings in BPD (Thébaud 2007). Various animal models of impaired alveolar development also display abnormal lung vascular development (Thébaud 2007). Vascular endothelial growth factor (VEGF) is required not only for the formation but also the maintenance of the pulmonary vasculature and alveolar structures throughout adulthood (Thébaud 2007). In lung tissue from infants who died from BPD, the typical patterns of alveolar simplification with dysmorphic microvasculature are associated with reduced lung VEGF and VEGFR-1 mRNA and protein exposure (Lassos et al. 2001). Babies with RDS, compared with healthy subjects, have an excess of neutrophils and alveolar macrophages in their lung effluent.

Baro/volutrauma and oxygen toxicity induce an inflammatory reaction, which persists in babies who develop BPD; 95% of 11–15-day-old babies with BPD have neutrophils in their aspirates. The activated neutrophils mediate endothelial cytotoxicity and inhibit phosphatidylcholine synthesis (Zimmerman 1995). During the acute phase of lung injury, a host response is initiated (Odezmir et al. 1997). Proinflammatory cytokines (interleukin (IL)-1 β , IL-6) (Kotecha et al. 1996) and soluble intercellular adhesion molecule 1 (ICAM-1) are demonstrated in the lung lavage from day 1, reaching a peak in the second week. IL-1 β activity also increases during the first week, inducing the release of inflammatory mediators, activating inflammatory cells and upregulating adhesion molecules on endothelial cells. There is release of chemokines, including the α -chemokine IL-8, which induces neutrophil chemotaxis, and the

β -chemokine macrophage inflammatory protein (MIP)-1- α , which is chemotactic for monocytes and macrophages. High concentrations of MIP-1- α have been associated with the later development of fibrosis (Murch et al. 1996b). The anti-inflammatory cytokine IL-10 partly regulates the production of tumour necrosis factor- α , IL-6 and IL-8. Sequential bronchoalveolar lavage (BAL) samples over the first 96 hours demonstrated that IL-10 mRNA was absent, possibly predisposing to chronic lung inflammation (Jones et al. 1996).

Inflammatory mediators can induce an isoform of haemoxygenase (HO), an enzyme that catalyses the rate-limited oxidative cleavage of haemoglobin. Carbon monoxide (CO) is produced endogenously as a byproduct of that reaction. Oxidative stress also significantly increases HO-1 expression in several pulmonary cell types, including macrophages, epithelial, endothelial and fibroblast cells. End-tidal CO levels were higher on days 7, 14, 21 and 28 in infants developing BPD and an end-tidal CO level >2.15 ppm on day 14 had 80% sensitivity and 92% specificity in predicting oxygen dependency at 36 weeks' PMA (May et al. 2007).

Mediator release from the neutrophils may increase airway hyperreactivity, as the BAL fluid contains elevated levels of lipid mediators, including leukotrienes (Mirro et al. 1990; Groneck et al. 1993), which cause bronchoconstriction, vasoconstriction, oedema, neutrophil chemotaxis and mucus production in the lung. Leukotriene B₄ (LTB₄), the anaphylatoxin C5a and IL-8 have been detected in the BAL fluid of BPD infants (Groneck et al. 1994).

There are increased concentrations of the soluble form of ICAM-1, a glycoprotein that allows cell-to-cell contact, in the tracheal aspirates of babies with early BPD (Kojima et al. 1993). Levels of soluble E-selectin, another cell adhesion molecule, are also increased in the perinatal period in babies developing BPD (Ramsay et al. 1998). Direct contact between activated cells leads to further production of proinflammatory cytokines and other mediators. The inflammatory infiltrate is associated with striking loss of endothelial, basement membrane and interstitial sulphated glycoaminoglycans (Murch et al. 1996a). Glycoaminoglycans are important in restricting albumin and ion flux, inhibiting fibrosis in fetal animals and controlling cellular proliferation and differentiation.

Differential diagnosis of bronchopulmonary dysplasia

Viral pneumonia, aspiration problems and lung infections due to immune deficiency can usually be differentiated from BPD on the history. The changes in the CXR appearance due to either total anomalous pulmonary venous return or pulmonary lymphangiectasia are present from birth.

Management

General

The aim is to keep the baby free from infection, while gradually weaning the baby off the ventilator and into progressively lower concentrations of oxygen. It is important to ensure that older babies have a comprehensive care plan, which includes attention to appropriate auditory, tactile and visual experiences and the opportunity to suckle. The provision of sleep–wake rhythms is also important. Parental support is essential through these prolonged admissions. Home oxygen therapy allows early discharge, except in those babies who require intermittent positive-pressure support or are failing to gain weight. Babies who remain chronically ventilator-dependent should be transferred to a ward more suited to dealing with older infants.

Ventilator management

The peak inspiratory pressures and inspired oxygen concentrations should be kept at the minimum compatible with achieving a P_{aO_2} of 6.7–9.3 kPa (50–70 mmHg) and oxygen saturations of at least 92% (Ch. 19). In infants with evidence of pulmonary hypertension, the oxygen saturation level should be maintained at least at 95%. Ventilator rates over 60 breaths/min using a conventional ventilator offer no advantage to babies developing BPD (Chan et al. 1991). After the first week, increasing the positive end-expiratory pressure level to 6 cmH₂O can improve oxygenation without adversely affecting CO₂ elimination (Greenough et al. 1992a), but this strategy may not be successful in babies with severe cystic BPD. CO₂ levels can be allowed to rise, provided that there is no evidence of a respiratory acidosis (that is, a pH less than 7.25). Sedation should be kept to the minimum, as the aim is to promote the infant's respiratory efforts so that the baby can become independent of the ventilator. Certain babies, despite appropriate respiratory support, suddenly become grey, pale, sweaty and cyanosed, frequently associated with poor chest wall expansion (BPD spells). Affected babies are difficult to ventilate by bag and mask and may take many minutes to resuscitate. These episodes seem to occur in agitated babies. Simultaneous measurements of tidal flow, airway and oesophageal pressure and oxygen saturation demonstrated that the hypoxaemic episodes were preceded by an active exhalation and a decrease in end-expiratory lung volume, which could lead to small-airway closure and the development of intrapulmonary shunts (Bolívar et al. 1995). Sedation can help to reduce the number of episodes, but if they are very frequent and troublesome it may be necessary to paralyse affected babies. High-volume strategy, high-frequency oscillation (HFO) can improve oxygenation in babies who deteriorate acutely, but may cause overexpansion in those who have cystic BPD.

Babies with BPD may require prolonged ventilation. Chronic use of either an oral or nasal endotracheal tube can result in cosmetic defects (Ch. 44). Tracheostomy avoids those problems and eases nursing of an increasingly active infant. Tracheostomies, however, may be difficult to close in this population (Ch. 27.7); thus, their use should be restricted to babies who remain fully ventilated after 3 months of age.

Weaning

Frequent attempts should be made to wean the baby from the ventilator. During weaning, a rise in P_{aCO_2} should be ignored, unless the pH falls below 7.25. Methylxanthines may be useful to hasten weaning. Corticosteroids facilitate extubation (Halliday and Ehrenkranz 2003), but their short-term beneficial effects have to be weighed against possible long-term adverse effects. Extubation initially should be attempted after a short period for up to an hour on endotracheal CPAP, to ensure that the infant has adequate respiratory drive (p. 529). Nasal CPAP may be poorly tolerated in relatively mature babies (Chan and Greenough 1993), but is useful for those who have acquired tracheobronchomalacia (Panitch et al. 1994). If nasal CPAP is required for prolonged periods, it is important that an appropriate method of fixation is used (Ch. 44). Reintubation and ventilation should be avoided, unless the baby suffers frequent troublesome or a major apnoea, severe metabolic acidosis indicating respiratory fatigue or a marked deterioration in blood gases. Physiotherapy and increasing the inspired oxygen concentration should be the first-line treatment for worsening blood gases, which will usually be due to atelectasis associated with secretions.

Oxygen therapy and monitoring

Administration of supplementary oxygen via nasal cannulae has advantages regarding ease of nursing care, but the exact oxygen concentration is difficult to monitor and, as a consequence, this mode of delivery should not be used in babies at risk of retinopathy.

Transcutaneous oxygen monitoring significantly underestimates arterial P_{O_2} in babies with BPD. Oxygen saturation monitoring is preferred, as, over a wide range of P_{aO_2} , P_{aCO_2} , pH, heart rate, blood pressure, haematocrit and fetal haemoglobin levels, a close correlation between pulse oximeter values and arterial S_{aO_2} at saturations greater than 78% has been demonstrated (Ramanathan et al. 1987). Chronic intermittent hypoxia may result in increased pulmonary vascular resistance, pulmonary hypertension and right heart failure and, in non-randomised studies, administering supplementary oxygen to keep the oxygen saturation at >92% was associated with a better growth rate and a reduction in hospital admissions. Aiming for higher saturations in the majority of babies with BPD, however, has apparent disadvantages. In a trial examining the efficacy and safety of supplemental therapeutic oxygen for babies with pre-threshold retinopathy of prematurity, those maintained at saturations of 96–99% rather than 89–94%, had an increased risk of adverse pulmonary events, including pneumonia and/or exacerbations of BPD (STOP-ROP Multicenter Study Group 2000); the trial, however, was not designed to assess pulmonary outcomes. In a subsequent multicentre double-blind randomised trial, 358 infants were allocated to oxygen saturations of 91–94% or 95–98% (Askie et al. 2003); no significant differences were found in weight, length, head circumference or major developmental abnormalities at 12 months of corrected age. The high saturation group, not surprisingly, required supplementary oxygen for a longer period after randomisation and had a higher rate of dependence on supplementary oxygen at 36 weeks' PMA and a significantly higher frequency of home-based oxygen therapy (Askie et al. 2003). There is an ongoing study assessing the outcome of infants randomised to 85–90% and 91–95% oxygen saturations (BOOST II). Our policy is for babies with BPD who are more than 1 month old to have an echocardiograph to determine whether they have pulmonary hypertension. If detected, then their oxygen saturations are maintained at least at 95%; if pulmonary hypertension is not present, then the oxygen saturation is maintained at least at 90%.

Cardiovascular status

BPD babies can develop pulmonary hypertension, thus a routine echocardiographic examination is recommended. Pulmonary hypertension can be indicated clinically by a single heart sound and the murmur of tricuspid regurgitation, but an easily palpable liver may simply reflect hyperexpanded lungs. Although cardiac catheterisation of babies with BPD is not routinely indicated, it can be used to assess the responsiveness of the pulmonary vascular bed to changes in the oxygen tension (Abman et al. 1985). If the pulmonary artery pressure falls with a rise in oxygenation, continuous oxygen therapy by nasal cannula should be used. Pulmonary hypertension may also be detected non-invasively by echocardiography.

Systemic hypertension is common in BPD babies and can appear after discharge. Hypertension may result from renal damage following prolonged umbilical artery catheter usage or nephrocalcinosis due to chronic diuretic therapy. In addition, certain medications, including corticosteroids (Greenough et al. 1992b), elevate the blood pressure. Although the hypertension is frequently transient and responds to antihypertensive medication (Emery and Greenough 1992), it can result in left ventricular hypertrophy.

Infection

Chest infections occur frequently in babies with BPD (Yüksel and Greenough 1992a) and should be treated with physiotherapy, antibiotics or antiviral therapy, as appropriate. The respiratory tract of a baby with BPD is frequently colonised with potentially pathogenic bacteria and it is important to differentiate this from true infection. If there is a deterioration in respiratory status or radiological appearance (Fig. 27.47), endotracheal or nasopharyngeal secretions should be cultured. In addition, nasopharyngeal secretions should be sent to determine if the infant has a viral infection. If a respiratory syncytial virus (RSV) infection is identified and other causes of a respiratory deterioration have been excluded (for example a PDA; Fig. 27.48) treatment with ribavirin should be considered (Giffin et al. 1995).

Fig. 27.47 Deterioration due to *Staphylococcus epidermidis* infection; note the left upper lobe consolidation. The baby has metabolic bone disease.

Fig. 27.48 Chest X-ray of an infant with bronchopulmonary dysplasia and a patent ductus arteriosus. Note the widespread lung changes.

Routine immunisations, but a killed polio vaccine, should be given once BPD babies reach 2 months of age, even though they remain on the neonatal intensive care unit. Immunisation against influenza should also be considered, especially for babies receiving home oxygen therapy. Immunoprophylaxis with palivizumab against RSV should be given for babies discharged home on supplementary oxygen.

Haematology

Babies who require an inspired oxygen concentration of greater than 30% should have regular packed cell volume (PCV) estimations and a transfusion (15 ml/kg) given if their PCV falls below 40%. Once respiratory support is no longer required, it is sufficient to check the haemoglobin level on a weekly basis and to transfuse only those babies who have symptomatic anaemia with a poor reticulocyte response (Ch. 30).

Fluid and electrolytes

Excessive fluid intake should be avoided. Babies with severe BPD usually will not tolerate more than 150 ml/kg/24 h. If their weight gain is greater than 20 g/kg/24 h on such a regimen, this may indicate heart failure and regular diuretics should be considered. If chronic diuretic therapy is given, acid-base balance, chloride and calcium levels must be carefully monitored and appropriate supplements administered if these become abnormal. Regular renal ultrasounds should be performed to check for the development of nephrocalcinosis.

Nutrition

Babies with BPD require a calorie intake approximately 20–40% greater than age-matched infants without respiratory embarrassment. Energy requirements, however, above 150 kcal/kg are rare and usually associated with malabsorption (Reimers et al. 1992). For further general advice on nutrition, see Chapter 16.

Feeding problems depend on the severity of BPD; infants with BPD have poor feeding coordination, feeding endurance and performance (Mizuno et al. 2007). Babies with BPD can suffer from aspiration and gastro-oesophageal reflux. This can be difficult to manage. The osmolality should be checked if thickeners are used with a concentrated feed. Other feeding problems are common and include tiring on feeding and vomiting. Oral hypersensitivity can occur and results from repeated negative stimuli to the oral area and lack of development of appropriate feeding behaviour.

Drug therapy

Diuretics

Administration of furosemide can acutely increase lung compliance and reduce airway resistance (Kao et al. 1983; Najak et al. 1983), facilitating a reduction in ventilator requirements (McCann et al. 1985) and transient improvements in blood gases in both ventilated and non-ventilated babies (Kao et al. 1984a, 1994). Systematic review of studies, however, demonstrated that, in preterm babies less than 3 weeks of age with BPD, furosemide administration had either inconsistent or no detectable effects (Brion et al. 2006). In babies older than 3 weeks, a single dose of 1 mg/kg of furosemide improved lung compliance and airway resistance for 1 hour. Chronic administration of furosemide also improved both oxygenation and lung compliance, but the positive effects were limited to the duration of the treatment. Prolonged therapy with hydrochlorothiazide and spironolactone had been suggested to be

useful in hypertensive BPD babies (Abman et al. 1984) and to improve the outcome of babies with severe BPD (Albersheim et al. 1989). Unfortunately, those results were not confirmed in randomised trials (Brion et al. 2008), lung mechanics were improved and the need for furosemide was reduced, but no long-term benefits were demonstrated in infants receiving current therapy.

Diuretics have many side-effects. Furosemide increases the urinary excretion of sodium, chloride and potassium and consequently may cause hypochloraemia, hyponatraemia and hypokalaemia, in addition to hypocalcaemia (McCann et al. 1985). It may also cause a metabolic alkalosis (De Rubertis et al. 1970), and compensatory hypoventilation and hypercarbia have been described (Hazinski 1985). Other side-effects include secondary hyperparathyroidism, rickets and ototoxicity (Rybak 1982). In adults, the ototoxicity of furosemide is related to its plasma concentration and there is a synergistic effect with aminoglycosides. Chronic diuretic therapy may cause hypercalciuria, renal calcification and nephrolithiasis (Hufnagle et al. 1982). Nephrocalcinosis is commonest in the most immature babies and those receiving the longest course of therapy or given furosemide by the intravenous route (Short and Cooke 1991). Other risk factors for nephrocalcinosis include a family history, fluid restriction, total parenteral nutrition or methylxanthine administration, and renal candidiasis. Nephrocalcinosis is associated with urinary tract infection and haematuria and, at follow-up, chronic glomerular and tubular dysfunction.

Aerosolised furosemide has been given to babies with or developing BPD (Kugelman et al. 1997), the rationale being that lung mechanics in patients with lung oedema might be improved by diuresis-independent lung fluid reabsorption and/or there may be alleviation of reactive airway disease, as occurs in adults and children. Systematic review of results of studies in which a single dose of aerosolised furosemide was given demonstrated significant improvement in tidal volume after 1 and 2 hours, but no improvement in compliance or resistance at either time point (Brion et al. 2006). A dose of 1 mg/kg appears more effective than lower doses (Rastogi et al. 1994). The review concluded that in infants both less than and older than 3 weeks of age there is insufficient information to determine whether a single dose of aerosolised furosemide improves outcome or lung function.

Methylxanthines

Intravenous aminophylline therapy can improve lung function and hasten weaning from the ventilator in babies with BPD, but only in those less than 30 days old (Rooklin et al. 1979). The lack of response in the older age group might be explained by extensive pulmonary fibrosis resulting in irreversible airways obstruction. Oral theophylline can improve lung function in BPD babies; the addition of a diuretic is synergistic (Kao et al. 1987).

Bronchodilator therapy

Inhaled bronchodilator can reduce airways resistance in babies with BPD at term (Kao et al. 1984b; Motoyama et al. 1987; Wilkie and Bryan 1987) and improve pulmonary resistance, dynamic compliance, tidal volume and transcutaneous blood gases when administered to ventilated babies with BPD at approximately 1 month of age (Caball et al. 1987). Salbutamol administration results in a dose-related improvement in lung mechanics in ventilator-dependent babies; the beneficial effects of 200 µg salbutamol last 3 hours (Denjean et al. 1992). Inhaled ipratropium bromide gives similar short-term improvements (Wilkie and Bryan 1987). Synergism occurs between ipratropium bromide and salbutamol in improving respiratory mechanics in ventilated babies for up to 1–2 hours after administration (Brundage et al. 1990). No synergy,

however, was shown between metaproterenol and atropine, and with both treatments lung function returned to baseline values within 3 hours (Kao et al. 1989). There are no randomised trials with long-term outcomes in which treatment with bronchodilator had been initiated before discharge from the neonatal unit (Ng et al. 2001).

After discharge, inhaled bronchodilators administered via a spacer device can improve lung function and reduce symptoms in wheezy VLBW survivors (Yüksel et al. 1990; Yüksel and Greenough 1991). Nebulised bronchodilator, however, may cause a deterioration in lung function, as evidenced by an increase in airways resistance (Yüksel et al. 1991b); this can be avoided by administering the bronchodilator by inhaler and spacer device (Yüksel and Greenough 1991). Although individual BPD babies may benefit from bronchodilator administration, routine treatment is not warranted in stable patients. In such patients with a corrected age of 1 year, neither salbutamol nor ipratropium bromide resulted in a significant reduction in pulmonary resistance (De Boeck et al. 1998).

Disodium cromoglycate

Disodium cromoglycate both has an anti-inflammatory effect and reduces non-specific bronchial hyperactivity. At follow-up, disodium cromoglycate can reduce symptoms and bronchodilator usage in VLBW infants (Yüksel and Greenough 1992b).

Corticosteroids

Steroids have a number of beneficial actions, including stabilising membranes and reducing pulmonary oedema, enhancing surfactant synthesis, suppressing collagen synthesis and reducing bronchospasm and inflammation in small airways and leukotriene production. Dexamethasone given to ventilated babies reduces the pulmonary inflammatory response, microvascular permeability and release of inflammatory mediators and neutrophil influx into the airways (Groneck et al. 1993). If corticosteroids are started after 3 weeks of age, the positive effects are a significant reduction in BPD at 36 weeks' PMA and a reduction in failure to extubate by 28 days, need for late rescue dexamethasone and home oxygen therapy (Halliday and Ehrenkranz 2001).

Numerous side-effects of steroid therapy have been reported. These include sepsis, necrotising enterocolitis, hyperglycaemia, hypertension, diabetic ketoacidosis, hypertrophic cardiomyopathy and greater weight loss (Pomerance and Puri 1980; Gunn et al. 1981; Regev et al. 1987; Noble-Jamieson et al. 1989; Israel et al. 1993; Spear et al. 1993; Rastogi et al. 1996). Nosocomial infection may be more likely to occur in babies in whom treatment is commenced at 2 rather than 4 weeks of age (Papile et al. 1998). In addition, dexamethasone used prior to 14 days of age has been associated with an increased risk of candidal sepsis (Pera et al. 2002). It is important, therefore, to exclude sepsis before embarking on steroid therapy, but a policy of prophylactic antibiotics or antifungal agents to run concurrently is not evidence-based. Dexamethasone can cause secondary adrenal suppression at the hypothalamic-pituitary level (Cronin et al. 1993).

The possible long-term effects of corticosteroids are of concern. In animal models, corticosteroids significantly impair cell multiplication in the lung and central nervous system. Dexamethasone given to rats at a critical period after birth (4–14 days) resulted in increased lung volumes, enlarged air spaces and reduced alveolar surface area and total DNA content. After the drug was withdrawn, the trend towards precocious puberty was reversed, but late sequelae were described, that is, emphysematous lungs with larger and fewer air spaces (Tschanz et al. 1995). In animal models, decreased brain weight and DNA content have also been reported, with a delay in

cortical dendritic branching and disrupted postnatal glial cell formation. There have, however, been concerns regarding the possible adverse long-term neurodevelopmental effects of systemically administered corticosteroids (Ch. 3). The risk may be related to the timing of administration: meta-analysis of 20 randomised trials demonstrated that only early and not late treatment was associated with a significant excess of cerebral palsy (Doyle et al. 2010). No significant effect was seen on the incidence of cerebral palsy when corticosteroids were administered after 3 weeks (Halliday et al. 2003). In the trials, however, when corticosteroids were administered late, greater crossover occurred, and this may have obscured any effect (Doyle et al. 2010).

Another factor which increases adverse outcome is the steroid dosage. In one study (Wilson-Costello et al. 2009) each 1 mg/kg of corticosteroid was associated with a 2.0-point reduction in the Mental Development Index and a 40% increase in disabling cerebral palsy. In that study, older PMA was not found to mitigate the adverse effect and treatment after 33 weeks' PMA was associated with the greatest harm. High-risk compared with low-risk BPD babies, however, experienced less harm (Wilson-Costello et al. 2009). Spastic diplegia appears to be the most common form of cerebral palsy following dexamethasone administration. Concerns regarding the side-effects of corticosteroids have resulted in a decline in their use over the last 10 years; this has been associated with an increase in BPD (Yoder et al. 2009). It has been suggested (Eichenwald and Stark 2007) that it is reasonable to consider a therapeutic trial of corticosteroids in infants with life-threatening respiratory disease who require substantial ventilatory support and supplemental oxygen ($\text{FiO}_2 > 0.8$). Before treatment, parents should be informed of the potential benefits and the uncertain additional risk of neurological injury (Eichenwald and Stark 2007). The respiratory status of an infant who is responsive to corticosteroids will usually improve over the first 2–3 days of treatment, thus we would not continue the therapy if there had been no response after 72 hours. If they do respond, a 7–10-day course is recommended (Eichenwald and Stark 2007). The optimum dosage is uncertain, although 0.15 mg/kg/day has been suggested (Eichenwald and Stark 2007).

In view of the concerns regarding systemically administering corticosteroids, the efficacy of this therapy by the inhaled route has been investigated. Meta-analysis of four trials in which inhaled steroids were given to infants older than 14 days demonstrated improved extubation success, with no increase in sepsis (Lister et al. 2010). In one randomised trial, which included infants with moderate BPD, fluticasone inhalation versus placebo did not reduce the duration of ventilation or supplementary oxygen dependency; however, the trial was only powered to detect a difference of at least 21 days (Dugas et al. 2005). Meta-analysis of five randomised trials comparing inhaled versus systemic steroids administered to ventilator-dependent infants with evolving BPD after 2 weeks of age demonstrated no significant differences in the incidence of BPD at 36 weeks' PMA or the duration of intubation or oxygen dependency (Shah, S.S. et al. 2007).

Surfactant

Surfactant dysfunction may persist and contribute to the continuing respiratory support required by neonates with BPD. In a pilot study, a single dose of a natural surfactant reduced the inspired oxygen concentration requirement in babies aged between 7 and 30 days (Pandit et al. 1995).

Inhaled nitric oxide

Inhaled nitric oxide (iNO) may be useful in infants with or developing BPD to reduce their oxygenation index, but the magnitude of

response can be variable and the optimum dose ranges from 6 to 60 ppm (Lonnqvist et al. 1995). In the absence of a demonstrated well-defined risk-to-benefit ratio for the use of long-term pulmonary vasodilators, it has been suggested that their administration should be restricted to patients with pulmonary arterial pressure at or near systemic levels with evidence of right ventricular dysfunction (Kulik et al. 2010).

Recommendations regarding drug therapy

A single dose of furosemide should be given to treat acute fluid overload, and regular chlorothiazide and spironolactone administered to infants who have signs of incipient right heart failure or are poorly tolerant of a modest fluid volume regimen (120 ml/kg/day). Caffeine, commenced to facilitate extubation, should be continued until at least 36 weeks' PMA and only stopped before if symptomatic gastro-oesophageal reflux develops. On the neonatal intensive care unit, bronchodilators are rarely necessary and should be administered only to those BPD infants who have symptomatic wheeze and their respiratory support requirements are reduced as a consequence of bronchodilator administration. We consider corticosteroids only for infants who are at least 2 weeks of age and have severe lung disease, remaining ventilator-dependent and in high oxygen concentrations. Systemic corticosteroids are prescribed for 3 days and only continued, for a further 7 days in a reducing dose, if there has been an obvious clinical response (i.e. a significant reduction in respiratory support requirements). Research is required to determine if there is a dosage regimen with a positive risk-to-benefit ratio. Other drug therapies, discussed above, are used only on an individual basis or in the context of a randomised trial.

Home respiratory support

Home oxygen therapy should be considered for babies who have no medical problem other than their increased inspired oxygen requirement. Some parents, however, will also cope with tube feeding their baby. This facilitates earlier discharge from the neonatal unit and, if there is appropriate support in the community, does not lead to increased readmissions (Greenough et al. 2004). Supplementary oxygen can be delivered via either a single feeding catheter inserted into one nostril or twin nasal cannulae. Oxygen concentrators should be used, unless the baby requires only low amounts of oxygen. Small portable oxygen cylinders should also be provided, whichever system is used, as they are necessary for transporting the baby. At regular intervals, the baby should be seen at home or in hospital and progress and weight checked. The baby's oxygen saturation needs to be monitored preferably for at least 24-hour periods on a regular basis, aiming to maintain saturation levels of above 92% unless there is pulmonary hypertension. Weaning from supplementary oxygen should be gradual; if the inspired oxygen concentration is abruptly reduced, resulting in hypoxaemia, this can lead to worsening pulmonary hypertension and an increased incidence of apnoea, which responds to improving arterial oxygen saturation (Sekar and Duke 1991). It is essential to ensure that patients maintain their oxygen saturation levels at all times; desaturation occurs particularly after feeding (Singer et al. 1992) and lower oxygen saturation levels may be recorded when the baby is asleep.

For the first month after oxygen is no longer needed, parents should keep the equipment at home in case of increased oxygen need associated with even minor respiratory infections. Home oxygen facilitates earlier discharge from the neonatal unit and corresponding financial savings, but can have an adverse impact on the family's quality of life (McLean et al. 2000). It is important to be

aware that some infants may require months or up to 2 years of supplementary oxygen at home (Greenough et al. 2006). Even after they no longer require home oxygen, such patients still are more symptomatic and require more treatment (Greenough et al. 2006).

Only a small number of babies with BPD have been discharged on home ventilation (Fauroux et al. 1995). The babies must have a tracheostomy. Home ventilation requires an enormous investment in equipment, community services and education for parents (Panitch et al. 1996).

Prophylaxis

Antenatal therapy

Corticosteroid treatment given to women at high risk of preterm delivery reduces the incidence of neonatal death and RDS by approximately 50% (Crowley et al. 1990), but, even in combination with postnatal surfactant, fails to have a favourable impact on the incidence of BPD (Jobe et al. 1993). The positive effects of thyrotrophin-releasing hormone seen in early studies (Ballard et al. 1992) have not been confirmed in large randomised trials.

Fluid management

Promotion of an early diuresis with a diuretic (Savage et al. 1975) or an albumin infusion (Greenough et al. 1993) does not significantly improve perinatal respiratory status. Fluid restriction in the first weeks after birth does not reduce BPD (Bell and Acarregui 2008), but does reduce the risks of PDA and necrotising enterocolitis and, in the largest study (Kavvadia et al. 2000) included in the meta-analysis, fluid restriction was associated with a significant reduction in the use of postnatal steroids. In a retrospective analysis (Oh et al. 2005) of 1382 infants, higher fluid intake and less weight loss during the first 10 days after birth were associated with an increased risk of BPD. Limiting colloid administration and avoiding early sodium supplementation might reduce the incidence of BPD. Inverse relationships between the amount of colloid received and perinatal lung function (Kavvadia et al. 1999) and the risk of BPD development (Dimitriou et al. 2002) have been demonstrated. A lower rate of BPD was noted in infants in whom sodium supplementation was not given in the first 3–5 days compared with those receiving daily maintenance sodium (Costarino et al. 1992). In addition, in a randomised trial, withholding sodium supplementation until there was evidence of weight loss equalling 6% of birth weight, rather than giving routine maintenance, was associated with a reduction in the proportion of babies who required supplementary oxygen at 7 days (Hartnoll et al. 2000).

Indometacin

In the randomised trial including 1202 ELBW infants, indometacin prophylaxis, although reducing the incidence of symptomatic PDA by 50%, did not reduce the incidence of BPD, defined as the need for supplementary oxygen at 36 weeks' PMA (Schmidt et al. 2001). Subsequent analysis demonstrated that prophylactic use of indometacin was associated with higher supplementary oxygen requirement and less weight loss by the end of the first week after birth (Schmidt et al. 2006b).

Corticosteroids

Commenced in the first 96 hours after birth, corticosteroids reduce the risk of BPD at both 28 days' and 36 weeks' PMA, lower the risk of PDA and pulmonary airleak and promote earlier extubation (Halliday and Ehrenkranz 2003). Seven trials have examined the efficacy of administration between 7 and 14 days; the overall result

was a reduction in BPD and facilitation of extubation (Halliday et al. 2003). Recent studies have focused on determining the efficacy of low-dose dexamethasone; dexamethasone administered as 0.89 mg/kg over 10 days facilitated extubation without obviously increasing side-effects, but did not reduce the incidence of BPD (Doyle et al. 2006). No difference was demonstrated in death or major disability at 2 years, but the number of infants included in the study was small (Doyle et al. 2007) and further studies are required to assess this approach.

An alternative approach has been to use the inhaled route. Review of randomised trials assessing the efficacy of inhaled steroid therapy initiated in the first 2 weeks after birth demonstrated no statistically significant effects on BPD at 28 days' or 36 weeks' PMA or on mortality (Shah, V. et al. 2007). There was, however, a reduction in the requirement for rescue systemic steroids. Meta-analysis of randomised trials demonstrated that early inhaled steroids did not confer any important advantage over systemic steroids in the management of ventilator-dependent preterm infants (Shah, V. et al. 2007). In a pilot study, early intratracheal instillation of budesonide using surfactant as a vehicle was associated with a significant reduction in the combined outcome of death or BPD (Yeh et al. 2008). Side-effects are less common with inhaled steroids (Halliday and Ehrenkranz 2001); they include tongue hypertrophy but this resolves after cessation of treatment (Linder et al. 1995).

Hydrocortisone

No reduction in BPD has been demonstrated in randomised trials (Doyle et al. 2010) and one trial was halted prematurely as the hydrocortisone-treated infants had an increased rate of gastrointestinal perforation (Watterberg et al. 2004).

Methylxanthines

Caffeine

In a large randomised trial, caffeine administration to infants at risk for or having apnoea of prematurity or to facilitate removal of an endotracheal tube was associated with a significant reduction in BPD (36% versus 47%) (Schmidt et al. 2006a). In addition, in the caffeine group, positive airway pressure was discontinued 1 week earlier and a significantly lower proportion required treatment for a PDA. Caffeine administration was associated with a reduction in the risk of PDA deemed to need either pharmacological or surgical closure. Follow-up demonstrated that the caffeine-treated group had a higher rate of survival without neurodevelopmental disability at 18–21 months (Schmidt et al. 2007).

Pentoxifylline

This is a methylxanthine derivative and non-selective phosphodiesterase inhibitor with anti-inflammatory effects. In a randomised trial of 150 VLBW infants, pentoxifylline administration was associated with a 27% reduction in BPD (Lauterbach et al. 2006).

Azithromycin

Azithromycin is a newer generation macrolide and has fewer side-effects and increased anti-inflammatory properties than erythromycin. Azithromycin significantly reduced IL-6 and IL-8 production by tracheal cells obtained from prematurely born infants. BPD, however, was not significantly reduced by azithromycin given for a maximum of 6 weeks in a double-blind placebo-controlled trial which included 43 infants of birthweight less than 1001 g, but postnatal steroid use was lower in the treatment group (31% versus 62%, $p = 0.05$) (Hazinski et al. 1989). Potential side-effects include late-onset infections, particularly fungal sepsis, hepatotoxicity and hearing impairment.

Vitamin E

Vitamin E is a scavenger of free radicals. The toxic effects of oxygen upon the lung are enhanced by vitamin E deficiency and can be prevented by vitamin E treatment (Taylor 1956). Healthy term and premature babies have mean plasma vitamin E levels of less than 0.25 mg/dl in the first 24 hours after birth (Moyer 1950); a level of less than 0.5 mg/dl indicates vitamin E inadequacy in adults. Daily vitamin E administration to infants requiring an inspired oxygen concentration of greater than 40% was associated with a reduction in the number of babies with a CXR appearance compatible with BPD (Ehrenkranz et al. 1978). Meta-analysis of 26 randomised trials demonstrated that vitamin E supplementation does not reduce the risk of BPD and high-dose intravenous vitamin E supplementation increased the rate of sepsis (Brion et al. 2003). Vitamin E decreases the oxygen-dependent intracellular killing ability of neutrophils, resulting in a decreased resistance to infection in preterm babies (Johnson et al. 1985). Infants whose mothers had received high-dose vitamins E and C during pregnancy in a large multicentre randomised trial did not have an improved respiratory outcome; indeed they had higher healthcare utilisation in the first 2 years after birth (Greenough et al. 2010).

Vitamin A

Vitamin A supplementation influences the normal differentiation of regenerating airways. VLBW infants are frequently deficient in vitamin A because of deprivation of transplacental acquisition. In addition, parenteral administration of vitamin A is inefficient (Chan et al. 1993) because of photodegradation and absorption of the vitamin to the intravenous tubing. VLBW neonates with BPD may have suboptimal plasma concentrations of vitamin A for extended periods (Shenai et al. 1985). In a randomised study (Shenai et al. 1987), vitamin A (retinyl palmitate 2000 IU), given by the intramuscular route on postnatal day 4 and every other day thereafter for a total of 14 injections over 28 days to oxygen-dependent babies, resulted in significantly higher mean plasma concentrations of vitamin A and a reduction in BPD and the need for supplementary oxygen, mechanical ventilation and intensive care. The results of subsequent trials have been conflicting (Pearson et al. 1992; Shenai 1999; Tyson et al. 1999), but meta-analysis of the results of eight randomised trials (Darlow and Graham 2008) highlighted that vitamin A supplementation reduced death or oxygen requirement at 1 month of age and oxygen requirement at 36 weeks' PMA. In six of the studies, vitamin A was given by intramuscular injection and neurodevelopmental outcome was only available for one of the studies. Vitamin A administration must be carefully monitored if side-effects, such as non-specific neurological signs secondary to raised intracranial pressure caused by toxic levels, are to be avoided. The optimal dosage, mode and duration of administration of vitamin A in VLBW babies need further investigation.

Superoxide dismutase

Superoxide dismutase (SOD) is a naturally occurring intracellular enzyme which converts the toxic superoxide radical into the potentially less toxic hydrogen peroxide. Pretreatment of rats with SOD prevented toxic changes in lung macrophages (Simon 1980) and damage to lung cells (Block and Fisher 1977) when exposed to hyperoxia. Human neonates are deficient in SOD (Northway 1979; Yoshioka et al. 1979). The efficacy of prophylactic SOD has been tested in a randomised trial (Suresh and Soll 2002); no favourable effect on oxygen dependency at 28 days' or 36 weeks' PMA was noted. In one study, however, treated babies, compared with those who received placebo, had a 36% reduction in repeated episodes

of wheeze severe enough to require antiasthma medication in infancy (Davis et al. 2003). Toxicity has not been reported, but antioxidant therapy may affect the bactericidal activity of polymorphonuclear cells.

N-acetyl cysteine

The immature lung is deficient in glutathione synthesis (Jain et al. 1995), which is limited by the availability of cysteine. N-acetylcysteine (NAC) is a stable precursor of cysteine. Glutathione is an endogenous scavenger of free radicals and hence has a major role in the antioxidant defence system of the lung. In a multicentre double-blind placebo-controlled trial (Ahola et al. 2003) which included 391 infants of birthweight less than 1 kg, no significant differences were found in the incidence or severity of BPD between those who received NAC for 6 days and those who received the placebo.

Allopurinol

Allopurinol is a synthetic competitive inhibitor of xanthine oxidase and a free radical scavenger. Enteral administration of 20 mg/ml for 7 days, in a randomised placebo-controlled trial, however, failed to reduce the incidence of BPD significantly (Russell and Cooke 1995).

Melatonin

Melatonin is a potent free radical scavenger. In a randomised study, infants with RDS who received 10 intravenous injections of melatonin had significantly lower levels of proinflammatory cytokines and reduced ventilatory requirements during the prenatal period (Gitto et al. 2005).

Surfactant

Overall, exogenous surfactant replacement therapy, although significantly reducing the combined outcome of BPD and death, does not reduce the incidence of BPD alone. Early surfactant therapy with extubation on to nasal CPAP compared with selective rescue surfactant therapy and continued mechanical ventilation was associated with a lower rate of BPD (Stevens et al. 2007).

Inositol

Inositol promotes maturation of surfactant phospholipids and the synthesis of phosphatidyl inositol. Meta-analysis of two randomised trials demonstrated that inositol supplementation, although reducing the combined outcome of BPD and death, did not reduce BPD (Howlett and Ohlsson 2003).

Bronchodilators

Prophylaxis with salbutamol, started in the first 2 weeks after birth, was not associated with a significant reduction in the duration of ventilatory support, incidence of BPD or mortality (Ng et al. 2001).

Cromolyn sodium

Cromolyn sodium inhibits neutrophil activation and neutrophil chemotaxis and thus can modulate the inflammatory process in the lung (Ng and Ohlsson 2002). In a randomised trial (Watterberg and Murphy 1993), however, prophylactic cromolyn sodium failed to reduce significantly the incidence of BPD or any other clinically important outcome.

Ambroxol

In one study, ambroxol given over the first 5 days was associated with a 50% reduction in the incidence of BPD, without adverse effect (Wauer et al. 1992).

Triiodothyronine

In a randomised, placebo-controlled trial, administration of triiodothyronine and hydrocortisone for 7 days after birth to infants of less than 30 weeks' gestation was not associated with a reduction in BPD (Biswas *et al.* 2003).

Respiratory support

In non-randomised studies, use of CPAP rather than intubation and ventilation was associated with a lower rate of BPD. In a large randomised trial (COIN), which included 610 infants born at 25–28 weeks of gestation, although infants randomised to CPAP had a lower risk of death or need for oxygen therapy at 28 days, there was no significant difference in the rates of oxygen dependency at 36 weeks' PMA and the pneumothorax rate was significantly greater (threefold) in the CPAP group (Morley *et al.* 2008). The INSURE (intubation–surfactant–treatment–extubation) method is a combination of early surfactant treatment and early extubation on to CPAP. Meta-analysis of six trials demonstrated that such an approach compared with selective surfactant with continued ventilation in infants with RDS was associated with a significant reduction in BPD, need for mechanical ventilation and airleaks (Stevens *et al.* 2007). A larger proportion of the infants in the early compared with the selective surfactant group received surfactant. It is well documented that prophylactic/early surfactant versus selective/rescue surfactant once RDS is established reduced the incidence of BPD/death and airleaks and improved survival in 208 infants born between 25 and 28 weeks' gestational age and this questions whether the effects seen were due to early surfactant, early CPAP or both. In a randomised study (Sandri *et al.* 2010), prophylactic surfactant (200 mg/kg Curosurf) and extubation within 1 hour if possible was associated with similar results with regard to need for mechanical ventilation in the first 5 days (31.4% versus 33%) as nCPAP (6–7 cmH₂O) to selective surfactant given if there was CPAP failure (48.5% required surfactant at median 240 minutes). In addition, there were no significant differences in other outcomes (Sandri *et al.* 2010). In another trial, amongst infants born before 28 weeks of gestation, intubation and surfactant within 1 hour and extubation within 24 hours compared with CPAP (5 cmH₂O) and rescue surfactant in the first 48 hours resulted in no significant differences in BPD or death (54.1% versus 48.7%), although less of the latter group received surfactant (SUPPORT Study Group 2010). Those studies suggest that, if CPAP is used from birth, the short-term advantages of early versus delayed administration of surfactant become less apparent, but whether the long-term outcomes are similar needs to be investigated.

Permissive hypercapnia reduces ventilatory requirements, but infants randomised to target P_{CO_2} ranges of 55–65 versus 35–45 mmHg had a higher incidence of BPD or death and significantly increased combined outcome of mental impairment at 18–22 months or death (Thome *et al.* 2006). Meta-analysis of the results of randomised trials has demonstrated that patient-triggered ventilation does not reduce the incidence of BPD (Greenough *et al.* 2008). Meta-analysis of the results of randomised prophylactic trials of HFO ventilation (HFOV) in which infants were randomised to receive HFOV or conventional mechanical ventilation in the first 12 hours after birth demonstrated that HFOV was associated with a modest but significant reduction in BPD (Henderson-Smart *et al.* 2007). The trials, however, differed with respect to administration of antenatal corticosteroids and postnatal surfactant and the types of oscillator and conventional ventilator used. The results of a non-randomised study suggested that HFOV may protect small-airway function (Hofhuis *et al.* 2010). Follow-up at school age, when

comprehensive respiratory and neurodevelopmental assessments can be undertaken, is needed to determine whether HFOV may have long-term benefits.

Nitric oxide

Inhaled nitric oxide (iNO) selectively decreases pulmonary vascular resistance and improves oxygenation. In addition it has anti-inflammatory effects and promotes cell and vessel growth in the immature lung (Kinsella *et al.* 1997). Infants dying with BPD have been noted to have disrupted pulmonary vasculature, hence a vascular hypothesis for the development of BPD has been proposed (Abman 2001) and that modulation of angiogenic growth factors might reduce BPD (Thébaud *et al.* 2005). Indeed, in an animal model (Tang *et al.* 2004), inhaled NO stimulated angiogenesis and alveolarisation. Meta-analysis of 11 randomised trials demonstrated that the effect of iNO in prematurely born babies depends on the timing of administration and the population (Barrington and Finer 2007). Early rescue treatment based on oxygenation criteria did not affect mortality or BPD rates and there was a trend towards an increase in intracerebral haemorrhage. Early, routine use for intubated infants, however, was associated with a just significant reduction in the combined outcome of death or BPD and a reduction in the incidence of severe intracerebral haemorrhage and periventricular leukomalacia. In a subsequent large trial, in which preterm infants were randomised to early, prolonged, low-dose iNO therapy, no significant differences were demonstrated in any important outcomes (Mercier *et al.* 2010). Use of iNO after 3 days based on an elevated risk of BPD showed no effect on BPD (Barrington and Finer 2007).

Prognosis

Mortality

Predischarge mortality is usually caused by intercurrent infection, cor pulmonale or respiratory failure. Predictors of death in hospital include male gender and length of ventilatory support and supplementary oxygen (Shaw *et al.* 1993). Sudden infant death syndrome was reported to be higher in babies with BPD (Werthammer *et al.* 1982), but this has not been subsequently confirmed (Sauve and Singhal 1985; Gray and Rogers 1994).

Morbidity

Infants with BPD require a prolonged hospital stay and have delayed discharge home; in one population-based observational study, the adjusted lengths of stay for infants with and without BPD were 84 and 58 days respectively (Klinger *et al.* 2006). Prematurely born infants with BPD can require supplementary oxygen for many months or even years (Greenough *et al.* 2002), although few remain oxygen-dependent beyond 2 years of age (Greenough *et al.* 2006). Infants requiring supplementary oxygen at home have the most severe lung disease, as evidenced by their requirement for hospital readmission in the first 2 years after birth being twice that of non-home oxygen-dependent BPD infants (Greenough *et al.* 2002) and, even when they are no longer home oxygen-dependent, they still have more outpatient attendances and are more likely to wheeze and require an inhaler between 2 and 5 years of age (Greenough *et al.* 2006). BPD infants require a median of two (range 0–20) rehospitalisations in the first 2 years (Greenough *et al.* 2001). Rehospitalisations are significantly more common in BPD babies requiring supplementary oxygen at home (Greenough *et al.* 2002) and those who develop RSV infections (Greenough *et al.* 2001). The

hospitalisation rate, however, declines after the second year, such that hospitalisation was infrequent in prematurely born children at 14 years of age, regardless of BPD status (Doyle et al. 2001).

Morbidity relating to growth

The average weight and height at term of babies with severe BPD are frequently at or below the third centile; growth failure is partially the result of increased metabolic demands from increased work of breathing. Growth accelerates as respiratory symptoms improve. At school age, children who had had BPD did not have poorer growth than controls (Vlenich et al. 1995).

Central nervous system morbidity

Delays in development have been reported to be common, with poor developmental outcome correlating positively with prolonged hospitalisation and requirement for oxygen in babies with severe BPD. Developmental delay was reported to be commoner in BPD babies oxygen-dependent beyond 36 weeks' PMA than in those oxygen-dependent only beyond 28 days or less (Gregoire et al. 1998). Ventilation for longer than 28 days has been associated with intact survival, but not in VLBW babies with evidence of significant brain injury (Thomas et al. 2003b). Amongst children without severe gross motor delays, risk factors for BPD accounted for the association of BPD and developmental delay (Laughon et al. 2009). Significant abnormalities in brainstem auditory evoked responses have been reported in infants with BPD, indicating that both myelination and synaptic function in the auditory brainstem were impaired (Wilkinson et al. 2007).

Pulmonary morbidity

Recurrent respiratory symptoms requiring treatment are common in prematurely born children, particularly in those who had BPD (Greenough et al. 2006). In a cohort of 7–8-year-olds, whereas 30% of BPD children and 24% of prematurely born children without BPD were wheezing, only 7% of term controls were so affected (Gross et al. 1999). The most severely affected remain symptomatic in adulthood (Northway et al. 1990; Vrijlandt et al. 2005). Pulmonary function abnormalities in the first year after birth in BPD babies include high airways resistance, low dynamic pulmonary compliance, reduced functional residual capacity, abnormal gas exchange (hypercarbia, low oxygen saturation), elevated minute volume and lower gas-mixing index. The most consistent finding in BPD infants has been an increased pulmonary or airway resistance (Northway et al. 1967; Stocks et al. 1978; Morray et al. 1982; Yüksel et al. 1991b). In prematurely born infants, the number of days of wheeze significantly correlated with the degree of gas trapping (Broughton et al. 2007). Lung function usually improves with age (Morray et al. 1982; Wong et al. 1982; Gerhardt et al. 1987). Nevertheless, pulmonary function tests may still be abnormal, with reduced exercise tolerance, in school-age children (Smith et al. 2008). School-age children with BPD were demonstrated to have reduced absolute and size-corrected flow rates compared with controls matched for age and size (Filippone et al. 2003). A strong correlation was demonstrated between the maximum flow at functional residual capacity at 2 years of age and forced expiratory volume in 1 second (FEV₁) at school age, which suggests persistent airflow limitation in some patients with BPD. In adolescents, evidence of airways obstruction and hyperreactivity and an increased responsiveness to histamine (Doyle et al. 2001; Allen et al. 2003) and apparently asymptomatic BPD patients desaturating on exercise have been demonstrated (Santuz et al. 1995). Amongst the most severely affected, lung function abnormalities have been reported even in adolescents and young adults. A BPD cohort born between

1964 and 1973, as adolescents and young adults were significantly shorter and weighed less than term-born controls and a matched prematurely born cohort without BPD; 68% of the BPD cohort had airways obstruction and 52% had evidence of reactive airways disease (Northway et al. 1990). In a nationwide follow-up study in the Netherlands, the prevalence of doctor-diagnosed asthma was significantly higher in prematurely born 19-year-olds than in age-matched controls. There was, however, an effect of gender; whereas the 19-year-old women who had had BPD had more asthma (24% versus 5%, $p = 0.001$) and shortness of breath during exercise (43% versus 16%, $p = 0.008$) than controls, the prevalence of reported symptoms by men with BPD was comparable with the controls (Vrijlandt et al. 2005), probably reflecting the different patterns of thoracic growth between the sexes, which at the end of puberty results in approximately 25% higher lung function in males than females.

Numerous chronic complications may be seen on the CXRs of BPD infants at follow-up, including cor pulmonale, right ventricular hypertrophy and enlargement of the main pulmonary artery, reflecting pulmonary hypertension. Atelectasis and subsegmental or segmental collapse may occur, frequently affecting the left lower lobe. Rickets, due to dietary or parenteral nutritional deficiency of calcium and vitamin D or to the calciuric effect of furosemide, may manifest by rib fractures together with generalised demineralisation and metaphyseal fraying, widening and cupping. The CXR abnormalities of severe BPD may persist for some years. Most patients, however, remain either radiologically stable or show a trend towards improvement. High-resolution CT scanning demonstrated that adult survivors of 'traditional' BPD, compared with similar-aged young adults, had multifocal areas of reduced attenuation and perfusion, bronchial thickening and decreased bronchus-to-pulmonary artery diameter ratios (Howling et al. 2000). In one series, all young adults who had required supplementary oxygen at 36 weeks' PMA had abnormal CT findings: the most common finding (84% of cases) was emphysema, which inversely correlated with the FEV₁ z-score (Wong et al. 2008) and in another (Aukland et al. 2009) 86% of ELBW infants at 10 or 18 years had lung parenchymal abnormalities detected on high-resolution CT examination, which again correlated with impairment of lung function (FEV₁).

Cardiovascular morbidity

Pulmonary hypertension can be detected non-invasively by Doppler echocardiographic demonstration of tricuspid regurgitation or estimation of the pulmonary systolic time interval. Such measurements can be used to identify a response to elevation of the inspired oxygen concentration (Benatar et al. 1995). Infants with BPD and severe pulmonary hypertension are at high risk of death, particularly in the first 6 months after diagnosis (Khemani et al. 2007). Systemic hypertension is also common in babies with severe BPD, affecting 13% of 87 patients who required home oxygen therapy. In the survivors, however, it resolved prior to weaning from supplementary oxygen (Anderson et al. 1993).

Other forms of chronic lung disease

Wilson–Mikity syndrome

Prematurely born babies, classically who have had no respiratory problems in the first week after birth, are affected. The diagnosis is made when progressive respiratory failure develops during the second week, in association with diffuse small bilateral cystic translucencies on the CXR (Wilson and Mikity 1960). The babies have

intrapulmonary shunting and maldistribution of ventilation and perfusion (Krauss et al. 1970); pulmonary hypertension can be detected at cardiac catheterisation. Nowadays, this condition is rare and predominantly affects infants with a birthweight of less than 1500 g (Hoepker et al. 2008).

Clinical signs

There is an insidious onset of tachypnoea and cyanosis, and dyspnoea, especially on effort. The infant frequently has an overexpanded chest, wheezing and coughing.

Aetiology

The syndrome usually occurs in babies of less than 32 weeks' gestational age (Burnard 1966); it thus may represent a functional and anatomical immaturity of the airways (Saunders et al. 1978). Intrauterine infection may also be responsible, as babies with Wilson–Mikity syndrome have been found to have high plasma immunoglobulin M (IgM) levels on the first day after birth (Fujimura et al. 1983). In addition, the mothers of affected babies have been noted to have a high incidence of chorioamnionitis, in association with a raised cord blood IgM (Fujimura et al. 1989). Babies with a condition resembling Wilson–Mikity syndrome have been reported to have increased leukocyte elastase in tracheal aspirates at birth, indicating antenatal leukocyte migration to the lungs (Fujimura et al. 1993).

Diagnosis

A diffuse fine reticular pattern infiltrating both lung fields, interspersed with areas of emphysematous cysts, is seen on the CXR of

Fig. 27.49 Wilson–Mikity syndrome.

affected babies (Fig. 27.49). The changes initially, unlike in BPD, are more marked in the upper zones. As the disease progresses, the cysts coalesce and marked hyperinflation is a prominent feature.

Prognosis

Symptoms may persist for many months and respiratory infections are common during infancy. Abnormal lung function, suggesting persistent small-airway damage, has been found in survivors even at 8–10 years of age, but usually the pulmonary disease resolves. Death may occur as a result of cardiac failure, respiratory failure, infection or pulmonary hypertension.

Part 4: Apnoea and bradycardia

Simon Hannam

Introduction

Apnoea is a commonly encountered phenomenon on the neonatal unit, particularly in preterm babies. Episodes of cessation of breathing can lead to hypoxaemia and bradycardia requiring resuscitation. As there are many different causes of apnoea, the treatment of the condition depends on the results of investigation into, and diagnosis of, the underlying pathology.

Definition

The American Academy of Pediatrics defines apnoea as a pause in breathing of greater than 20 seconds or one of less than 20 seconds and associated with bradycardia and/or cyanosis (American

Academy of Pediatrics Taskforce on Prolonged Apnea 1978). A wide range of apnoea durations have been studied, varying from 2 (Hannam et al. 1998) to >15 seconds (Barrington and Finer 1990; Hodgman et al. 1990). In practice most apnoea alarms on neonatal units are set up to detect those apnoeas lasting for greater than 20 seconds. Apnoea must be distinguished from periodic breathing (see below), which is common in preterm infants and in which there are bursts of respiratory activity separated with apnoeic pauses lasting at least 3 seconds (Glotzbach et al. 1989).

Incidence of clinical apnoea

There is an inverse correlation between the frequency of apnoea and gestational age. Apnoea occurs in over 80% of babies born at less

than 30 weeks of gestation, about 50% of those born at 30–31 weeks, 14% born at 32–33 weeks and 7% born at 34–35 weeks (Henderson-Smart 1981).

Types of apnoea

There are three types of apnoea: central, obstructive and mixed. In central apnoea, there is a cessation of both respiratory effort and nasal airflow (Fig. 27.50A). With obstructive apnoea, nasal airflow ceases as the infant makes increasing respiratory effort in an attempt to overcome partial or total upper airway obstruction (Fig. 27.50B). The third type of apnoea is described as mixed and has both central and obstructive components. During central apnoeas, upper airway obstruction can occur, as reflected by the loss of cardiac artefact in the airflow trace (Milner et al. 1980). A reclassification of apnoea has been proposed using the presence or absence of amplified cardiac airflow artefact in the respiratory airflow trace to define whether an apnoea is central or obstructive (Lemke et al. 1996). Central apnoeas are those with the cardiac artefact present, obstructive where it is absent, and mixed where the artefact is absent during part of the apnoea (Lemke et al. 1998). The distribution of apnoea type has been demonstrated to vary with the length of apnoea in preterm infants (Butcher-Puech et al. 1985). Butcher-Puech et al. (1985) analysed 1520 episodes of apnoea of over 10 seconds' duration. With increasing length of apnoea, the proportion of central apnoea decreased from 69% to 29%, whilst that of mixed apnoeas increased from 20% to 60%. Pure obstructive apnoeas in preterm babies make up between 6% and 10% of the total number of apnoeas (Upton et al. 1991; Finer et al. 1992).

Mechanisms of apnoea

Central apnoea

Signals for the involuntary control of breathing which maintain rhythmic ventilation originate in the brainstem in the area of the medulla oblongata in the pre-Bolzinger complex. Input into the respiratory centre arises from three primary sources: chemoreceptors, mechanoreceptors of the lung and upper airway, and input from the cerebral cortex. Delayed maturation of any of these sites could potentially result in apnoea.

Brainstem generator

There is evidence for immaturity of the brainstem generator in the aetiology of apnoea of prematurity. In the preterm brain it has been demonstrated that, on histological examination, there were fewer synaptic connections, a reduced number of dendritic arborisations and a generalised reduction in myelination (Kattwinkel 1977). Functionally, brainstem conduction times, as detected by auditory evoked responses, have been shown to be faster with increasing gestational age (Henderson-Smart et al. 1983). Of interest, this slowing improves after treatment with aminophylline (Abu-Shaweesh and Martin 2008).

Chemoreceptors

Further evidence for dysfunction of the brainstem in apnoea has been reported in studies investigating the response of preterm infants to hypercarbia. Preterm infants who were having apnoeas had a depressed ventilatory response to CO₂ compared with those not having apnoeas (Gerhardt and Bancalari 1984a).

Hypoxic respiratory depression may play a role in apnoea of prematurity. Peripheral chemoreceptors located outside the brainstem in the carotid bodies near the bifurcation of the common carotid arteries receptors are primarily responsible for the ventilatory response to hypoxia. Preterm and newborn infants have been shown to exhibit an unusual pattern in their response to hypoxia in that they have an initial rapid increase in minute ventilation followed by respiratory depression (Martin et al. 1998). Several neurotransmitters have been implicated in the development of hypoxic respiratory depression. These include γ -aminobutyric acid (GABA), adenosine and endorphins (Martin and Abu-Shaweesh 2005). When the receptors for these neurotransmitters were blocked in animal models using bicuculline, methylxanthines or naloxone, respectively, the hypoxic respiratory depressive response was reduced. Experimental evidence suggests that adenosine and the inhibitory neurotransmitter GABA might interact with each other to cause apnoea (Abu-Shaweesh and Martin 2008). Blockading GABA_A receptors in piglets resulted in the reduction of an adenosine A_{2A} agonist-induced inhibition of phrenic nerve activity (Wilson et al. 2004). When the same adenosine agonist was administered directly into the cisternal system, there was inhibition of the phrenic nerve and stimulation of the laryngeal chemoreflex (LCR) (Abu-Shaweesh 2007).

A strong Hering–Breuer inflation reflex, as assessed by the prolongation of expiration following occlusion of the airway at end inspiration, has been demonstrated in preterm infants (Stocks et al. 1996). In contrast, the reflex has been shown to be significantly reduced in strength in preterm infants experiencing apnoea (Gerhardt and Bancalari 1984b). It is difficult to explain the increase in the strength of the Hering–Breuer inflation reflex in the preterm infants at term postmenstrual age as the newborn vagus nerve has a relatively few number of myelinated fibres and a smaller percentage of active slowly adapting receptors (Sachis et al. 1982; Fedorko et al. 1988). Alternatively, the inspiratory shortening might have been a reflection of a functional immaturity of the reflex arc responsible for the Hering–Breuer deflation reflex. The exact site of any defect in the reflex arc was not possible to identify. The effect of prematurity on the number and discharge properties of rapidly adapting receptors is not known. Fleming et al. (1978), however, demonstrated that preterm infants responded in an immature manner compared with term infants when they had gentle probing of the lower airway with a catheter. The Hering–Breuer deflation reflex (p. 456), which terminates expiration and promotes inspiration, has also been demonstrated to be immature in preterm babies having apnoeas (Fleming et al. 1978; Hannam et al. 1998).

Obstructive apnoea

Using the new classification of apnoea, many apnoeas previously described as being central are in fact obstructive or mixed in nature. Mechanisms leading to obstructed breaths include instability of the upper airway in preterm infants, asynchrony of the musculature of the upper airway and diaphragm, pathological changes in the upper airway and central nervous system pathologies. Obstruction of the upper airway may be a result of decreased tone in preterm infants, leading to collapse and obstruction of the upper airway (Idiong et al. 1998). Using an ultrafine fiberoptic scope, the site of upper airway obstruction in preterm babies has been shown to be at the laryngeal level (Ruggins and Milner 1991). It is not clear whether airway closure is a reflection of hypoxia associated with apnoea, whether it is due to asynchrony between the alae nasi and diaphragm sucking in the upper airway (Carlo et al. 1983) or whether it is due to passive airway narrowing due to reduced tone. Spontaneous neck flexion can also lead to obstruction in healthy preterm

Fig. 27.50 (A) Apnoea in a preterm infant born at 28 weeks of gestation recorded at 35 weeks' corrected gestational age. The recording was made using the Alice 4 sleep study system. In order from the top down, the traces represent: two scalp electroencephalograms (C3A1 and C4A2), two electro-oculograms (LEOG, REOG), electrocardiogram (ECG), oesophageal pH, nasal flow (FLW), abdominal movement (ABD), thoracic movement (THO) and oxygen saturation (SaO₂). Time in 5-second intervals is indicated at the bottom of the trace. As can be seen, there is a central apnoea lasting 6 seconds where there is cessation of nasal airflow movement and an absence of chest and abdominal wall movements. No desaturation or bradycardia was associated with this apnoea. (B) Obstructive apnoea in a different preterm infant, again born at 28 weeks of gestation with the recording made at 35 weeks' corrected gestational age. In this apnoea, lasting 5 seconds, chest wall movements continue in the absence of nasal airflow.

babies (Thach and Stark 1979) as well as in situations where there are anatomical abnormalities of the upper airway, such as Pierre Robin sequence and Down syndrome.

Mixed apnoea

With mixed apnoea, most apnoeas commence with central apnoea followed by airway occlusion (Idiong et al. 1998). Narrowing of the airway occurs about 1 second into a central apnoea (Lemke et al. 1998). This appears to be due to the loss of tone of the muscles of the upper airway. Clearly, this could then lead to the development of airway obstruction and evolve into a mixed apnoea. All apnoeas persisting for more than 20 seconds fall into the category of mixed apnoea (Upton et al. 1992a). Obstructing the airway can also lead to central apnoea. Upton et al. (1992b) investigated the response of preterm infants to airway obstruction. There was an increased frequency of central apnoea following relief of the obstruction, raising the possibility that obstruction itself might have a role in the development of the central apnoea (Upton et al. 1992b). Apnoea may represent an immaturity of the multiple mechanisms that determine the rate and depth of respiration (Waggener et al. 1984). A relationship between cycle time and length of apnoeic episodes has been demonstrated, reflecting a 'hunting' form of ventilation whereby respiration was first stimulated then suppressed. The fact that short respiratory pauses, periodic breathing and prolonged apnoeas all occur at the nadir of spontaneous breathing cycles (Waggener et al. 1989) supports the idea of a common aetiology of apnoea. In the light of recent studies, it appears that central, mixed and obstructive apnoeas are part of a spectrum of apnoea rather than forming distinct entities and that all may have a common underlying mechanism (Poets 2003).

Factors involved in apnoea

Most apnoeic episodes in preterm babies occur in preterm babies who are otherwise healthy. These are called primary apnoeas, can be attributed to prematurity and are a diagnosis of exclusion. There are many conditions that cause or accentuate apnoea (Table 27.14). It is therefore essential to investigate infants appropriately, with a high index of clinical suspicion, when apnoeas suddenly appear in a previously well baby.

Periodic breathing, sleep state and diaphragmatic fatigue

Periodic breathing can be defined as bursts of respiratory activity of 20 seconds or less, separated by central apnoeic pauses lasting from 3 to 10 seconds (Glotzbach et al. 1989). Periodic breathing is present in almost all preterm babies, but is relatively uncommon in term babies (Glotzbach and Ariagno 1992). The aetiology of periodic breathing remains obscure, although the finding that it is absent until 48 hours of age suggests that inactivity of peripheral chemoreceptors at this time might play a role (Barrington and Finer 1990). There is disagreement as to whether periodic breathing is a benign or harmful phenomenon. Desaturation during periodic breathing has been reported (Razi et al. 2002; Rigatto 2003), although whether this is of long-term significance is unclear. Previous research suggested that periodic breathing was not linked to prolonged apnoea in preterm babies (Barrington and Finer 1990). More recent studies have contradicted this finding and have proposed a causal link between periodic breathing and prolonged apnoea (Al-Saedi et al. 1997; Rigatto 2003). In both term and

Immunisation

preterm babies, periodic breathing and apnoeas are more common in rapid eye movement (REM) sleep than in non-REM sleep (Schulte et al. 1977). It has been suggested that the reason for this may be chest wall distortion stimulating the costophrenic inhibitory reflex (Knill and Bryan 1976), despite this distortion being present in both REM and non-REM sleep (Davi et al. 1979).

An alternative mechanism has been suggested in a study demonstrating that arterial oxygen levels were significantly lower in REM than in quiet sleep (Martin et al. 1979). It has also been demonstrated that sleeping position, but not type of sleep, was associated with central and obstructive apnoeas in preterm infants with central apnoeas being more common in the prone position (Bhat et al. 2006). Arousals and awakenings, as well as length of sleep, were

greater in the supine position. This suggested a connection between depth of sleep, sleeping position and apnoea.

Genetic predisposition

There is evidence that some infants may have a genetic predisposition towards experiencing apnoea of prematurity. A higher incidence of apnoea of prematurity in infants born to first-degree consanguineous parents has been demonstrated (Tamin et al. 2003). A genetic basis for apnoea of prematurity has also been suggested in a recent twin study (Bloch-Salisbury et al. 2010).

Hypoxia

As discussed previously, hypoxia tends to lead to respiratory depression in very immature babies. It therefore follows that any condition causing respiratory or neurological problems that lead to hypoxia can cause or accentuate apnoea in these babies. It has been demonstrated that preterm babies, with increasing levels of inspired oxygen, have decreasing apnoea frequency (Weintraub et al. 1992).

Infection

Apnoea is more likely to occur in an infected baby. The mechanism by which infection causes apnoea is unclear (Mathew 2003). Preterm infants infected with respiratory syncytial virus (RSV) are particularly prone to develop apnoea (Church et al. 1984).

Central nervous system disorders

Trauma, germinal matrix/intraventricular haemorrhage and meningitis are all associated with apnoea. Apnoea can also be a result of seizure activity (Watanabe et al. 1983). Apnoea can be associated with the Arnold–Chiari malformation. The rare condition of congenital central alveolar hypoventilation syndrome (Ondine's curse) is thought to be due to an abnormality of the neural crest cells involved in respiration, although a mutation in the *PHOX2B* gene in patients with this condition has been reported (Gaultier et al. 2004). Babies with this condition have absent ventilation sensitivity to hypoxia and hypercarbia even when they are awake. Their breathing pattern is normal when they are awake, but they become cyanosed when asleep. Prolonged respiratory support is required.

Environmental temperature

Preterm infants respond to an increase in environmental temperature beyond the thermoneutral range with a rise in apnoea frequency and periodic respiration (Perlstein et al. 1970). The mechanism for this is unclear.

Gastro-oesophageal reflux

Upper airway chemoreceptors may have a role in the development of apnoea. Instillation of saline into the airway of a sleeping infant induces apnoea, swallowing and arousal (Thach 1992). This response has been ascribed to the LCR being stimulated and, in preterm infants, an exaggerated LCR has been demonstrated (Pickens et al. 1988). Some authors feel that stimulation of the LCR plays an important role in apnoea of prematurity (Thach 2005). Of interest, the apnoea related to an exaggerated LCR might be connected to a predominance of GABA_A-related inhibitory pathways (Abu-Shawesh and Martin 2008). These responses could be

relevant when considering the role of gastro-oesophageal reflux (GOR) as a cause of apnoea. The association between GOR and apnoea of prematurity has been difficult to prove and recent studies have failed to demonstrate a temporal relationship between episodes of reflux and apnoea (Peter et al. 2002; DiFiore et al. 2005; Bhat et al. 2007). In support of this finding, treatment of GOR has not been shown to reduce the frequency of apnoea of prematurity (Kimball and Carlton 2001).

Apnoea and bottle feeding

Some infants, especially those with chronic lung disease, become hypoxaemic during and after bottle feeds (Rosen et al. 1984). It has not been possible to demonstrate an increased frequency of apnoea when comparing bottle, milk boluses via nasogastric tube, and continuous tube feeds (Poets et al. 1997).

Anaemia

If low levels of haemoglobin predispose infants to apnoea, blood transfusion should reduce the incidence of apnoea. A reduction in the incidence of apnoea following transfusion has been reported (Joshi et al. 1987). Other groups have not seen this response (Westkamp et al. 2002), and doubt remains regarding the efficacy of using transfusions to treat symptomatic apnoea.

Anaesthesia

Following a general anaesthetic, preterm infants are at risk of developing apnoea (Kurth et al. 1987). This problem worsens in preterm infants of increasing immaturity (Cote et al. 1995). As a result, postoperative monitoring in a high-dependency cot is essential for all preterm babies who are recovering from surgery, until they are at least a month postterm-equivalent postnatal age.

Patent ductus arteriosus

Infants who develop pulmonary oedema as a consequence of a patent ductus arteriosus are at risk of apnoea. Stimulation of pulmonary C fibres occurs in response to pulmonary oedema (Schertel et al. 1986), possibly leading to apnoea in a vagally mediated response.

Immunisation

Apnoea in preterm infants following immunisation with diphtheria, pertussis and tetanus (DPT) has been reported (Sanchez et al. 1997). For this reason, infants receiving immunisations on neonatal units need to be carefully monitored in the period following administration of vaccines.

Drugs

Analgesics such as morphine can depress neonatal respiration.

Bradycardia

As with apnoea, varying definitions of bradycardia in the preterm infant have been used by investigators. A fall in heart rate to less than 100 beats/min in a preterm infant for over 5 seconds is generally considered to constitute a bradycardia (Dransfield et al. 1983). Alternatively, a fall in heart rate of more than 30% below baseline

has been used as the criterion for bradycardia (Henderson-Smart et al. 1986; Poets et al. 1993). Whatever method of calculating a bradycardia is employed, a crucial factor to take into consideration is whether or not a bradycardia is clinically significant. Brief falls in heart rate unaccompanied by apnoea or desaturation are unlikely to be of importance. Bradycardias are more common in apnoeas of longer duration (Henderson-Smart et al. 1986).

A series of complex physiological interactions leads to the scenario of apnoea, bradycardia and desaturation (Martin and Fanaroff 1998). In the majority of cases, there is an apnoea or period of hypoventilation closely followed by a fall in oxygen saturation and then bradycardia (Adams et al. 1997). Initially it was thought that this bradycardia was the direct result of myocardial hypoxia. It is now clear that the bradycardia occurs too early in apnoea to be due to this effect (Vyas et al. 1981). Almost all bradycardias commence after the onset of apnoea and after the onset of the fall in oxygen saturation (Poets et al. 1993). This would support the theory that the bradycardia occurs via the carotid chemoreceptors. Upper airway closure may also have a role in the development of the bradycardia, perhaps due to the lack of stimulation of a pulmonary inflation reflex (Upton et al. 1992c). This has been shown by the heart rate not recovering in mixed apnoea until airflow had been restored (Henderson-Smart et al. 1986).

A different scenario exists whereby bradycardia occurs simultaneously with apnoea. This presumably represents a vagally mediated, rather than hypoxic, response. It has been proposed that enhanced vagal tone might have a role in predisposing preterm infants to apnoeas and bradycardias (Mathew 2003). The diving reflex could be the reflex pathway for this type of bradycardia (Daly 1986). This reflex can be initiated by immersing the face in ice-cold water, which causes stimulation of the trigeminal nerve (Scholander 1963) and results in apnoea, bradycardia and peripheral vasoconstriction. This dramatic reflex can be harnessed clinically to terminate episodes of supraventricular tachycardia (Ch. 8).

Monitoring

Monitoring is essential in babies who have conditions that predispose them to having apnoea. This includes all infants of less than 35 weeks of gestation and those more mature infants with other serious illnesses. There is some controversy as to the type of monitoring that is most appropriate in such babies. Based on the current evidence, we use a combination of a pressure-sensitive apnoea mattress, heart rate monitoring and oxygen saturation monitoring in our special-care nursery.

Cardiorespiratory monitoring (Ch. 19)

Owing to the close association between bradycardia and apnoea, all babies who are at risk of apnoea should have monitoring of heart rate as well as respiratory effort. This can be achieved using standard electrocardiogram monitors using three electrodes, two of which can be in common with impedance equipment. There can be problems with false alarms due to either detachment of one of the electrodes or body movement. The heart rate signal from a pulse oximeter is even more prone to false alarms.

There are several devices available that monitor the movement of the chest or abdominal wall. Techniques for assessing chest wall movement include: air-filled apnoea mattresses (Lewin 1969), pressure-sensitive devices which lie under the infant (Smith and Scopes 1972), pressure-sensitive capsules attached to the abdominal wall (Valman et al. 1983) and sensors that detect changes in abdominal circumference (impedance monitor and respiratory

inductance plethysmography). The first three types of devices are bedevilled by problems with false-positive alarms, which increase the stress placed on nursing staff and parents. Also, none is able to discriminate between obstructive/mixed apnoea and central apnoea. For this to be possible, a means of measuring nasal airflow, such as a nasal thermistor (Dransfield and Fox 1980) or an end-tidal CO₂ monitor, needs to be used. Impedance monitoring involves measuring the current that passes between two low-voltage electrodes placed on opposite sides of the chest. As the infant inspires, there is an increase in the air/tissue ratio and the voltage falls. This system does have the disadvantage of picking up changes in cardiac output during an apnoea and preventing the triggering of the alarm (Southall et al. 1998).

Respiratory inductance plethysmography consists of light-weight bands placed around the chest and the abdomen. Within the bands are coils of copper wire that act as a one-turn transducer. As the cross-sectional area of the chest and abdomen vary with respiration, so does the inductance of the bands. These variations can then be displayed. Paradoxical movements of the chest and abdomen, where the chest and abdomen move out of phase, can be used to diagnose obstructive apnoea accurately. Transthoracic impedance measurements cannot be used for this purpose (Brouillette et al. 1987).

Oxygenation

Babies who are receiving oxygen treatment must have the concentration measured, and their response to oxygen treatment must be assessed. This may be achieved using direct blood gas estimations, transcutaneous (tc) oxygen measurements or pulse oximetry. Pulse oximeters are easy to site, although care has to be taken not to attach the device too tightly. There is a faster response time than with tcPO₂ measurements, with the oximeter signal averaged over 3–5 seconds (Hay et al. 1989). The monitors are susceptible to both movement artefact and poor cardiac output, which can lead to false alarms. Pulse oximetry is of additional value as preterm infants can have episodes of profound desaturation in the absence of apnoea or bradycardia (Poets et al. 1995). In our view, a pulse oximeter is probably the most helpful single device to use when monitoring for apnoea on the neonatal unit. A combination of a cardiorespiratory monitor and pulse oximeter should be used in infants who are having symptomatic apnoeas (Upton et al. 1991).

Investigation of apnoea

Investigating a preterm baby who is developing apnoea depends to a great extent on the overall clinical picture. Most apnoeas in preterm babies will be related to immaturity and be primary apnoea. This is, however, a diagnosis of exclusion and apnoea can herald the onset of serious disease. Therefore, the following investigations should be considered: infection screen (including lumbar puncture and urinalysis), serum glucose, serum calcium, haemoglobin, chest X-ray, cranial ultrasound scan, arterial blood gas and viral screen (especially RSV). If the apnoeas remain resistant despite treatment, the presence of a convulsive disorder should be considered and an electroencephalogram obtained.

Treatment of apnoea of prematurity

Once a preterm baby has been investigated and appropriately treated for conditions aggravating apnoea, other therapies to decrease the frequency of apnoea need to be initiated.

Treatment of individual episodes of apnoea

Most babies respond to conservative treatment of an apnoea. Once an apnoea or bradycardic episode has been detected, usually by a monitor alarming, the baby needs to be assessed urgently. Many of these episodes are self-limiting and no action needs to be taken. If the baby is still apnoeic or bradycardic when examined, a gentle stimulus such as flicking the foot may be sufficient to restore breathing. If it is suspected that the baby might have aspirated a feed, the head should be gently extended and gentle suctioning of the upper airway should be attempted. If, despite these interventions, the baby remains apnoeic or the heart rate is not restored, the baby should be ventilated using either a bag and mask or a mask and T-piece using the baby's usual F_{iO_2} . This resuscitation should never be done using 100% oxygen, owing to the risk of retinopathy of prematurity with hyperoxaemia. Careful monitoring of the baby's oxygen saturations should be maintained throughout. Occasionally, intubation is required despite these manoeuvres.

Pharmacotherapy

Methylxanthines (caffeine and aminophylline/theophylline) form the mainstay of the treatment of apnoea of prematurity. The exact mechanism by which these drugs exert their effect is not known, although there is competitive antagonism at the adenosine receptor between xanthines and adenosine (Herlenius et al. 1997). A possible central mechanism of action for methylxanthines in preventing apnoea via blockade of the adenosine A_{2A} receptors on GABAergic neurons has been proposed (Abu-Shaweesh and Martin 2008). This would effectively decrease the release of GABA and reduce its inhibitory effect on breathing (Abu-Shaweesh and Martin 2008). As well as their effects on apnoea, methylxanthines act by increasing minute ventilation, improve CO_2 sensitivity, decrease hypoxic depression of breathing (Abu-Shaweesh and Martin 2008) and increase the strength of diaphragmatic contractility (Aubier et al. 1981). Levels need to be monitored closely. Theophylline is methylated to form caffeine in preterm babies and it may be necessary to monitor levels of both methylxanthines in order to assess the total drug load (Bory et al. 1979).

The most commonly encountered side-effect of theophylline is tachycardia. Less frequent side-effects include seizures, abdominal distension, vomiting, diarrhoea, jitteriness and worsening of GOR. Many units are now using caffeine as their first-line therapy instead of theophylline. This is partly due to caffeine having a wider therapeutic range with fewer toxic side-effects, although significant tachycardia can still be a problem. Routine blood levels are not required, providing the infant shows a satisfactory response to treatment. Caffeine treatment is associated with a significant reduction in apnoeas in preterm infants experiencing symptomatic apnoea (Erenberg et al. 2000; Henderson-Smart and Steer 2002). Although caffeine treatment of apnoea has a similar clinical response rate to theophylline, fewer infants experience adverse effects when caffeine is used (Henderson-Smart and Steer 2010).

A recently completed randomised controlled multicentre trial investigated the short- and long-term effects of caffeine versus placebo in a large group of preterm infants with birthweights between 500 and 1250 g (Schmidt et al. 2006, 2007). The benefits of caffeine therapy were demonstrated in that those treated had reduced incidences of bronchopulmonary dysplasia, cerebral palsy and developmental delay. The main side-effect was that of poorer weight gain in the treatment group.

Doxapram, which acts as a non-specific stimulant of the central nervous system, has been used as a second-line treatment in preterm babies who failed to respond to aminophylline (Barrington et al.

1986). Side-effects include abdominal distension, irritability, jitteriness, vomiting, increased blood pressure and feed intolerance. Although doxapram reduces the number of apnoeas in the first 48 hours of its administration, there is no evidence to support its use as a first-line agent in the treatment of apnoea of prematurity above methylxanthines in current-day practice (Henderson-Smart and Steer 2004).

Ventilation

If, despite treatment with methylxanthines, an infant continues to have frequent apnoeas, continuous positive airway pressure (CPAP) needs to be considered. CPAP reduces the incidence of apnoea by around 50% (Speidel and Dunn 1976). The effect of CPAP is selective – it reduces the incidence of mixed or obstructive apnoea but has no effect on central apnoeas (Miller et al. 1985). It is possible that CPAP exerts its effect through mechanically splinting the upper airway (Miller et al. 1990). On direct visualisation of the upper airway, CPAP has been demonstrated to dilate the laryngeal opening significantly (Gaon et al. 1999). Nasal intermittent positive-pressure ventilation (nIPPV) shows promise as a treatment of apnoea of prematurity and there is some suggestion that this method of ventilation might be more effective in preventing apnoeas than conventional CPAP (Lemyre et al. 2002). Further studies are required to investigate whether synchronising nIPPV will be of additional benefit. Occasionally, apnoeas are resistant to treatment and the infant has to be intubated and ventilated. In these infants, the lowest possible oxygen concentration and ventilatory pressures need to be used, as they are often relatively easy to ventilate.

Other therapeutic options

A variety of kinaesthetic stimulations to prevent apnoeas in preterm infants have been employed. These range from rocking beds to oscillating mattresses. There is little evidence that these methods are of any therapeutic value (Osborn and Henderson-Smart 2002). A recent trial was unable to demonstrate any benefit between altering the tilt of the infant versus applying kinaesthetic infant-handling techniques (Reher et al. 2008). Other measures, such as changing the position from supine to prone (Heimler et al. 1992; Kurlak et al. 1994), altering environmental temperature (Perlstein et al. 1970) and correcting hypoxia (Weintraub et al. 1992), can decrease the incidence of apnoea.

Stopping treatment, predischARGE monitoring and discharge home

Babies who have had apnoeas treated with methylxanthines tend to have had treatment discontinued by 35 weeks' postconceptional age (PCA) (Eichenwald et al. 1997). Despite this, significant apnoeas can persist up to 43 weeks' PCA (Eichenwald et al. 1997; Ramanathan et al. 2001). Most neonatologists agree that, after stopping methylxanthines, babies who have experienced problematic apnoea of prematurity should have an event-free period of 5–7 days before discharge from the neonatal unit (Darnall et al. 1997). On the neonatal unit, preterm babies are usually nursed in the prone position to improve oxygenation and reduce apnoea frequency (Heimler et al. 1992). Because of the increased risk of sudden infant death syndrome (SIDS) in the prone position, babies should spend a period of a week or more in the supine position prior to discharge, unless there are other factors that preclude this being done (Bhat et al. 2003).

Home monitoring

Infants who are born prematurely are at much greater risk of SIDS, with an almost sixfold increase in relative risk compared with term infants (Oyen et al. 1997). It was also shown that, if the preterm infant was nursed prone, there was a 50-fold increase in the risk for SIDS. It has been recommended that preterm infants who are experiencing symptomatic apnoeas should be discharged on home cardiorespiratory monitors (Little et al. 1987), although there is no evidence that those who have had troublesome apnoea on the neonatal unit are at additional risk of SIDS (Hoppenbrouwers et al. 2008). Most home cardiorespiratory monitors are unable to detect episodes of obstructive apnoea, due to their reliance on transthoracic impedance measurements. Obstructive apnoeas were the most commonly observed event detected in a series investigating the role of home monitoring in preterm infants (Ramanathan et al. 2001). However, even these apnoeas did not seem to be precursors to SIDS. At present, therefore, there seems little justification for using home monitoring in preterm infants.

Advice regarding SIDS and acute life-threatening events

Prospective cardiorespiratory monitoring carried out on preterm infants did not identify prolonged apnoea as a risk factor for SIDS (Southall et al. 1983). Despite this, prior to discharge of their baby from the neonatal unit, parents need to be advised of the measures that can be taken to reduce the risk of SIDS. These include placing the baby to sleep in the supine position, avoiding hyperthermia,

stopping smoking (Oyen et al. 1997) and not co-sleeping (Blair et al. 1999). Following discharge, a baby can occasionally experience an acute life-threatening event (ALTE). An ALTE is said to have occurred when a baby has been found apnoeic, with a change in colour (cyanosis or pallor) and tone (limpness or stiffness), and has required mouth-to-mouth resuscitation or vigorous stimulation. Ex-preterm babies are at increased risk of experiencing an ALTE (Ramanathan et al. 2001). For this reason, parents need to be taught basic infant life support prior to their baby being discharged.

Prognosis

A higher incidence of retinopathy of prematurity has been reported in preterm infants who have had troublesome apnoea (Purohit et al. 1985). It has, however, been difficult to prove that apnoeic episodes have a deleterious effect on neurological development. This is due to the presence of many confounding variables that might affect neurological outcome following intensive care on a neonatal unit. Some studies have found that apnoeas have an adverse effect on neurological development (Jones and Lukeman 1982; Butcher-Puech et al. 1985; Cheung et al. 1999) whilst others have not been able to demonstrate this association (Tudehope et al. 1986; Koons et al. 1993). There is an increasing body of evidence, however, that preterm infants who experience a high incidence of apnoea or have delayed resolution of apnoea have a worsened developmental outcome (Hunt et al. 2004; Janvier et al. 2004; Pillekamp et al. 2007).

Part 5: Malformations of the lower respiratory tract

Grenville F Fox

Pulmonary agenesis

Bilateral pulmonary agenesis is an extremely rare abnormality and is not compatible with postnatal life. It has been described in association with anencephaly and other congenital anomalies (Potter 1952).

Approximately 70% of cases of pulmonary agenesis are unilateral, occurring in association with other congenital anomalies, including congenital heart disease (CHD), oesophageal atresia, and vertebral and facial anomalies (Knowles et al. 1988; Osborne et al. 1989). Antenatal ultrasound diagnosis has been reported (Maymon et al. 2001), although most cases present with respiratory distress in the early neonatal period. Others may present with recurrent respiratory symptoms in early childhood or be discovered incidentally (Thomas et al. 1998).

Diagnosis is usually confirmed on a chest X-ray (CXR), which shows absence of aeration on the affected side, with marked mediastinal shift and herniation of the unaffected lung, which often shows compensatory hyperinflation.

Management is supportive, with treatment of other congenital malformations when possible. The mortality rate is high and often depends on coexisting CHD.

Pulmonary hypoplasia

Primary pulmonary hypoplasia

In this rare form of pulmonary hypoplasia, there is no apparent underlying cause. Familial cases have been described (Cregg and Casey 1997), although the disorder is usually sporadic. Acinar dysplasia has been found in some cases of primary pulmonary hypoplasia, with abnormal development occurring distal to the bronchi. There are no alveoli and the terminal bronchioles have multiple cystic branches lined by bronchial epithelium, equivalent to failure of lung development beyond the pseudoglandular phase (Rutledge and Jensen 1986).

Secondary pulmonary hypoplasia

A normal-sized thoracic cavity, normal amniotic fluid volume and normal fetal breathing movements are all required for optimal lung growth in utero. Causes of secondary pulmonary hypoplasia therefore include intrathoracic space-occupying lesions, small-chest syndromes, oligohydramnios and congenital neuromuscular disorders (Table 27.15).

Reduction in intrathoracic space

Conditions that restrict thoracic volume are frequently associated with pulmonary hypoplasia. Of these, congenital diaphragmatic hernia (CDH) has been extensively researched (Ch. 27.6), and histological studies show that this is associated with decreased

bronchial and vascular branching with reduced alveolar number (Dibbins and Weiner 1974).

Reduction in amniotic fluid volume

Oligohydramnios from any cause can result in pulmonary hypoplasia, particularly if it develops before 26 weeks' gestation (Table 27.15). Attempting to restore normal amniotic fluid volume by amniocentesis in some cases has been associated with less pulmonary hypoplasia, suggesting that adequate amniotic fluid volume is necessary for normal lung growth (Tranquilli et al. 2005).

Postmortem examination shows that pulmonary hypoplasia caused by oligohydramnios secondary to fetal renal disease results in a reduction in bronchial branching and decreased alveolar number and size. This indicates maldevelopment with onset prior to 16 weeks of fetal life, which continues into the third trimester (Hislop et al. 1979; Harrison et al. 1983).

Although not associated with severe pulmonary hypoplasia, amniocentesis in the first and second trimester may affect lung growth, leading to an increased incidence of respiratory problems and reduced lung volume and function in newborn infants (Anonymous 1978; Vyas et al. 1982; Thompson et al. 1992).

The mechanism for decreased lung growth due to oligohydramnios is uncertain and several mechanisms have been suggested, including thoracic compression (Tranquilli et al. 2005), decrease in fetal breathing movements (Adzick et al. 1984) and reduced stretching of the developing respiratory tract by fluid.

Reduction in fetal breathing movements

Pulmonary hypoplasia is associated with a number of congenital neuromuscular diseases. There is a reduction in bronchial branching, suggesting that lung growth and development are affected before the 16th week of fetal life. Fetal breathing movements are frequently seen with ultrasound scanning (USS) several weeks prior to this, and the amplitude of pressure changes during breaths has been shown to be an important determinant of normal lung growth (Liggins et al. 1981).

Clinical features

Bilateral pulmonary hypoplasia varies widely in severity. Those with mild disease may have minimal symptoms of respiratory distress, which resolve over the first few weeks of life without intervention (Aiton et al. 1996).

Severe bilateral pulmonary hypoplasia leads to significant respiratory failure, which is frequently complicated by pneumothorax and persistent pulmonary hypertension of the newborn (PPHN). When neuromuscular disease such as congenital myotonic dystrophy is present, there may be a history of reduced fetal movements and polyhydramnios due to poor fetal swallowing. Postnatally, there may be profoundly decreased muscle tone with myopathic

Table 27.15 Causes of secondary pulmonary hypoplasia

PATHOPHYSIOLOGY	CONDITION/AETIOLOGY
Reduction in intrathoracic space	Congenital diaphragmatic hernia (Areechon and Reid 1963) Congenital cystic adenomatoid malformation (Ostor and Fortune 1978) Congenital lung cysts Pleural effusions (Castillo et al. 1987) Small-chest syndromes (Table 27.15)
Reduction in fetal breathing movements	Congenital myotonic dystrophy (Vilos et al. 1984) Spinal muscular atrophy (Moerman et al. 1983) Phrenic nerve agenesis (Goldstein and Reid 1980) Cervical spinal cord lesions (Rotschild et al. 1994)
Reduction in amniotic fluid volume	Fetal renal abnormalities Bilateral renal agenesis (Potter syndrome) (Potter 1946) Multicystic dysplastic kidneys (Newbould et al. 1994) Polycystic kidney disease (Kaariainen et al. 1988; Newbould et al. 1994) Obstructive uropathy (Harrison et al. 1983) Renal tubular dysgenesis (Newbould et al. 1994; Kriegsmann et al. 2000) Prolonged premature rupture of membranes (Bain et al. 1964) Uteroplacental insufficiency Amniocentesis
Other	Rhesus disease (Chamberlain et al. 1977) Trisomies 21 (Cooney and Thurlbeck 1982) and 18 Maternal drugs Angiotensin-converting enzyme inhibitors (Hanssens et al. 1991) Sodium valproate (Janas et al. 1998) Anterior abdominal wall defects (Thompson et al. 1993a)

facies, talipes equinovarus, joint contractures and rib hypoplasia. Respiratory function is further compromised by diaphragmatic hypoplasia.

Congenital myotonic dystrophy is usually inherited in an autosomal dominant pattern via the mother, who is only mildly affected and often undiagnosed until presentation of her more severely affected baby. There may be a history of previous stillbirth or neonatal death (Ch. 41). The molecular basis of the condition is an expansion in the number of trinucleotide repeats at chromosome 19q13.3 (Brook et al. 1992).

Severe oligohydramnios due to renal disease or very early chronic leakage of amniotic fluid often causes severe pulmonary hypoplasia, resulting in early neonatal death. Affected neonates may be small for gestational age and have limb contractures and typical 'Potter's' facies with abnormal ears, flattened nose and epicanthic folds.

Diagnosis

Antenatal history and ultrasound may identify factors associated with pulmonary hypoplasia such as CDH and other causes of reduced intrathoracic space, bilateral renal anomalies and oligohydramnios or features of congenital neuromuscular disease (Table 27.15). Three-dimensional fetal ultrasonography and Doppler blood flow velocities of pulmonary arteries have been used to estimate lung volume (Lee et al. 1996; Yoshimura et al. 1999).

Severe bilateral pulmonary hypoplasia presents immediately after birth. Affected neonates are difficult to resuscitate, requiring high-pressure positive-pressure ventilation with $F_{I}O_2$ 1.0. Despite this, death often occurs within minutes of birth. The CXR shows small-volume lungs with a bell-shaped chest. Lung volumes can be estimated by measuring functional residual capacity using gas dilution or plethysmographic techniques (Thompson et al. 1992, 1993a; Aiton et al. 1996), although this is not routinely necessary as the diagnosis is usually established clinically with supporting radiological evidence.

Management

Antenatal

Antenatal diagnosis of conditions leading to pulmonary hypoplasia is often possible as early as the second trimester. This may provide an opportunity for antenatal fetal intervention in some cases. If polyhydramnios is present, drainage may prolong the pregnancy and reduce the risk and consequences of preterm birth.

Drainage of large fluid-filled congenital cystic adenomatoid malformations (CCAMs), bronchogenic cysts or hydrothoraces with a pigtail intercostal catheter used to create a thoracoamniotic shunt has been shown to be associated with resolution of hydrops and may allow normal subsequent lung growth (Thompson et al. 1993b; Lopoo et al. 1999).

Antenatal intervention for severe pulmonary hypoplasia by tracheal occlusion, usually with an inflated balloon, leads to entrapment of lung fluid which causes stretching of airways, with subsequent improved airway and pulmonary vascular growth (Ch. 27.6) (Harrison et al. 2001, 2003). Outcome from three centres following percutaneous fetoscopic endoluminal tracheal occlusion in 210 cases of severe pulmonary hypoplasia secondary to CDH, some with other associated anomalies, showed survival to hospital discharge of 48% (Jani et al. 2009). More information is given in Chapter 27, part 6.

Fetal tracheal occlusion has also been successful in preventing adverse neonatal outcome due to severe pulmonary hypoplasia in a small number of cases of oligohydramnios secondary to early second-trimester rupture of membranes (Kohl et al. 2009). Transabdominal amniocentesis has also been used for this indication, and evidence from one randomised controlled trial with intervention between 24 and 33 weeks' gestation suggested improved survival and less pulmonary hypoplasia following amniocentesis (Tranquilli et al. 2005).

Fetal bladder catheterisation has been carried out successfully in a number of cases of obstructive uropathy diagnosed prior to 24 weeks' gestation, thus avoiding pulmonary hypoplasia, due to resolution of severe oligohydramnios (Szaflik et al. 1998).

Postnatal

The degree of respiratory support required for infants with bilateral pulmonary hypoplasia depends on the severity of underdevelopment of the lungs. In many cases, particularly when there has been anhydramnios or severe oligohydramnios noted from early in the second trimester with other severe congenital anomalies such as bilateral cystic dysplastic kidneys, continued intensive care is usually futile and hence inappropriate. In cases of mild bilateral pulmonary hypoplasia, no respiratory support may be required and close monitoring is recommended over a period of several weeks or months while the lungs grow to a normal size (Aiton et al. 1996).

Many babies with bilateral pulmonary hypoplasia require prolonged mechanical ventilation. Ventilatory requirements may be high, particularly initially. Following prolonged rupture of membranes in the second trimester, some infants require very high-pressure ventilation initially, but recover rapidly over the first 24 hours of life to enable complete weaning from any respiratory support within a few days. This has been attributed to severe atelectasis due to oligohydramnios and is referred to as 'dry-lung syndrome' (McIntosh 1988). The lung growth in these cases is likely to be normal, but initial CXR appearance and antenatal history may suggest pulmonary hypoplasia (Losa and Kind 1998).

Owing to the increased risk of infection following prolonged rupture of membranes, broad-spectrum antibiotics should be given following appropriate investigations.

Pulmonary hypertension is a common problem. Inhaled nitric oxide, high-frequency oscillation, calcium antagonists and extracorporeal membrane oxygenation (ECMO) have been advocated, with successful outcome in some cases (Islam et al. 1999; Geary and Whitsett 2002). At 34 weeks, preterm delivery is low risk and may avoid joint contractures.

Prognosis

Survival with bilateral pulmonary hypoplasia is dependent on the degree of lung underdevelopment and other associated anomalies.

Resolution of symptoms due to mild to moderate pulmonary hypoplasia may take weeks to months (Aiton et al. 1996). Long-term ventilatory support may be required for those with more severe problems, with resolution likely to occur with growth; good nutrition is essential. Lung volume measurements using several different techniques in infants with a number of different underlying diagnoses have suggested that normal lung size is likely by 6 years of age in the vast majority who survive the early neonatal period (Chatrath et al. 1971; Thompson et al. 1990; Aiton et al. 1996).

Premature rupture of membranes prior to 26 weeks' gestation is associated with pulmonary hypoplasia in approximately 25% of cases (Everest et al. 2008). The gestational age at the time of membrane rupture was found to be most predictive of outcome, with duration of rupture (longer than 14 days) and severity of oligohydramnios also identified as risk factors for pulmonary hypoplasia in a meta-analysis of relevant studies (van Teeffelen et al. 2010). Previous reports suggested that premature rupture of membranes at less than 25 weeks' gestation resulted in neonatal mortality greater than 90% due to pulmonary hypoplasia (Kilbride et al. 1996). However, more recently published case series, in which antenatal steroids, postnatal surfactant, high-frequency oscillatory ventilation and inhaled nitric oxide were used, suggest that survival has improved to approximately 70% (Everest et al. 2008; Williams et al. 2009).

Small-chest syndromes

Table 27.16 shows conditions that have congenital chest wall abnormalities leading to respiratory symptoms in the neonatal period. The ribs are usually short and many are associated with vertebral anomalies resulting in kyphoscoliosis, which may further reduce thoracic volume. Pulmonary hypoplasia may also occur in some of these conditions, but lung growth and development have been documented as being normal in many cases (Williams et al. 1984).

Antenatal diagnosis using USS is able to detect many of these conditions before 24 weeks' gestation. In one series, accuracy of diagnosis was only 65%, but prediction of mortality had 100% sensitivity and specificity (Parilla et al. 2003).

Table 27.16 Congenital chest wall abnormalities causing neonatal respiratory symptoms

CONDITION	INHERITANCE/GENETICS	CLINICAL FEATURES	PROGNOSIS
Asphyxiating thoracic dystrophy (Jeune's syndrome)	Autosomal recessive – mutation in chromosome 15q13	Short ribs, bell-shaped chest, +/- short limbs, hypoplastic iliac wings, renal abnormalities	Variable severity ranging from mild neonatal respiratory distress and long-term survival, to early severe respiratory failure and death
Chondroectodermal dysplasia (Ellis van Creveld syndrome)	Autosomal recessive – mutation in chromosome 4p16	Short ribs, polydactyly (medial), congenital heart disease, cleft lip and palate, hypoplastic nails	Neonatal respiratory distress with good outcome
Short rib–polydactyly syndromes	Autosomal recessive	Short ribs, polydactyly, vertebral and pelvic defects, short limbs, congenital heart disease, renal, genital and intestinal abnormalities	Severe neonatal respiratory failure with early death
Achondroplasia	Autosomal dominant (80% new mutations)	Small chest, short limbs, macrocephaly with frontal bossing	Mild neonatal respiratory distress, upper airway obstruction and apnoea, mild hypotonia. Good prognosis

Table 27.16 Continued

CONDITION	INHERITANCE/GENETICS	CLINICAL FEATURES	PROGNOSIS
Achondrogenesis	Autosomal recessive	Type 1 (Parenti–Fraccaro syndrome) – short limbs, large head, small barrel-shaped chest with thin ribs with fractures, unossified vertebral bodies Type 2 (Langer–Saldino syndrome) – short limbs and ribs with more ossification of skull and vertebral bodies	Stillborn or die in early neonatal period
Thanatophoric dysplasia	Sporadic – fibroblast growth factor receptor 3 gene mutation	Very short limbs with ‘telephone handle’ femurs; very small, pear-shaped chest; clover-leaf skull; occasional other congenital anomalies (congenital heart disease, hydronephrosis, imperforate anus, hydrocephalus)	Severe neonatal respiratory failure usually leading to death within hours. Some may survive several weeks (O’Malley et al. 1972)
Camptomelic dysplasia	Autosomal recessive	Short limbs, bowed long bones, narrow thorax, occasionally with 11 ribs. May have female phenotype with male karyotype, hydrocephalus and hypoplasia of larynx and tracheal rings	Usually severe neonatal respiratory failure and early death within weeks. Survival to 17 years noted in one case (Spranger et al. 1970)
Osteogenesis imperfecta	Type II – usually autosomal recessive, but may be dominant. Mutation in type 1 procollagen genes	Severe deformity of the chest wall and limbs due to multiple, healed in utero fractures; soft skull, thin skin	Approximately 50% stillborn. Others usually die immediately after birth. Antenatal diagnosis by ultrasound scan (Morin et al. 1991) or chorionic villus biopsy possible
	Type III – autosomal recessive. Mutation in type 1 collagen genes	As above but less severe	Mild respiratory problems may occur in the neonatal period. Chest wall deformity is often progressive, resulting in death later in childhood in many cases
Hypophosphatasia (perinatal form)	Autosomal recessive – mutation in tissue non-specific alkaline phosphatase gene found in some cases (Gehring et al. 1999)	Poorly mineralised bones with multiple pathological fractures, short ribs and long bones, hypercalcaemia, low alkaline phosphatase	Death from respiratory failure in early neonatal period. Antenatal diagnosis possible by alkaline phosphatase assay from chorionic villus biopsy
Cleidocranial dysostosis	Autosomal dominant	Hypoplasia of clavicle, short ribs, delayed closure of anterior fontanelle and delayed eruption of teeth	Variable degree of neonatal respiratory distress may occur
Spondyloepiphyseal dysplasias	Autosomal dominant	Delayed ossification of vertebrae with kyphoscoliosis, small chest and cleft palate	May present with neonatal respiratory distress
Spondylothoracic dysostoses	Autosomal recessive	Vertebral anomalies resulting in severe chest wall deformity due to crowding of the ribs	Severe neonatal respiratory distress resulting in death within first few months (Karnes et al. 1991)
Spondylocostal dysostoses	Autosomal recessive or dominant	Vertebral and rib abnormalities resulting in some chest wall abnormality	Autosomal recessive type more likely to present with severe neonatal respiratory distress. Dominant form may present with mild symptoms only (Karnes et al. 1991)

Signs of respiratory distress may develop early in many of these conditions. The thorax often appears bell-shaped and the abdomen large. CXR shows the same, with short, horizontal ribs as well as apparent cardiomegaly and clear lung fields. Close examination of the vertebrae and other bones on a skeletal survey, along with detailed family history, may help establish the underlying diagnosis.

Four subtypes of short rib–polydactyly syndromes have been described (Saldino–Noonan, Majewski, Verma–Naumoff and Beemer–Langer syndromes), but these, along with asphyxiating thoracic dystrophy and Ellis van Creveld syndrome, are likely to represent variants of a single disorder (Martinez-Frias et al. 1993). This is supported by recent identification of the *DYNC2H1* gene mutation in both Verma–Naumoff and Ellis van Creveld syndrome (Dagoneau et al. 2009).

In many of these conditions, mechanical ventilation is often required immediately after birth and for a variable time, depending on the underlying diagnosis. Prognosis is often poor, but those surviving the first year may have a good long-term outlook (Oberklaid et al. 1977). Surgical reconstruction of the chest wall with bone grafts or synthetic prostheses has been described in cases of asphyxiating thoracic dystrophy and other similar conditions (Todd et al. 1986), with good long-term outcome being reported if this is limited to milder cases able to survive to 1 year of age before surgery is contemplated (Davis et al. 2001).

Congenital cystic adenomatoid malformation

CCAM is a rare condition, predominantly affecting the lower lobes of the lungs. These lesions have also been referred to as congenital pulmonary airway malformations and also, along with other variants, congenital lung and airway cysts and pulmonary sequestration, congenital thoracic malformations.

Unilateral CCAM is more common, more often affecting the left lung (Savic et al. 1979). Bilateral cases have also been reported (Sapin et al. 1997; Banerjee et al. 2002). The affected areas consist of a mass of cysts lined by bronchial or cuboidal epithelium, which may contain cystic and adenomatoid portions with intervening normal lung tissue. Stocker et al. (1978) described three pathological variations of CCAM. Type 1 is the most common of these, accounting for approximately 50% of cases. It consists of multiple, thin-walled cysts, lined with pseudostratified epithelium, which may contain mucus-secreting glands. The cysts are large and may be confused with congenital lobar emphysema. Type 2 CCAM accounts for approximately 40% of cases and consists of multiple, smaller cysts (less than 1–2 cm diameter), which are lined by ciliated cuboidal or columnar epithelium without glandular tissue. Type 3 lesions are rarer (less than 10% of CCAMs) and relatively solid lesions, which have very small cysts lined with ciliated cuboidal epithelium. Subsequently, a fourth type has been described which has acinar-alveolar epithelium, rather than the bronchiolar epithelium found in types 1, 2, and 3 CCAM (Morotti et al. 1999). This suggests that there are two subtypes of CCAM arising at different stages of the branching morphogenesis of lung development. The first arises at the pseudoglandular stage (types 1, 2 and 3), whilst type 4 lesions arise at the saccular stage. A simpler classification describing microcystic (cysts <5 mm) and macrocystic (cysts >5 mm) lesions has been suggested and also has prognostic value (Thorpe-Beeston and Nicolaides 1994).

The aetiology of CCAM remains obscure, although it has been suggested that it is the result of dysregulation of lung epithelial cell turnover, with both increased cell proliferation and decreased

apoptosis (Cass et al. 1998). Glial cell-derived neurotrophic factor is a growth factor involved in the development of fetal lung and other organs, and increased expression of this has been found in the epithelial cells of CCAM tissue compared with normal lung (Fromont-Hankard et al. 2002). Platelet-derived growth factor-BB (PDGF-BB) stimulates normal lung growth and is maximal during the canalicular stage. Increased levels of PDGF-BB have been found in rapidly growing CCAMs which were associated with hydrops (Fromont-Hankard et al. 2002).

The incidence of CCAM has been estimated at 1 in 25 000–30 000 pregnancies. Males and females are equally affected and there are no recognised patterns of inheritance. Trisomy 18 has been noted in a very small number of cases (Laberge et al. 2001). Associated congenital anomalies only occur in approximately 20% of cases (Stocker et al. 1978). Other congenital malformations of the lung such as bronchogenic cysts and pulmonary sequestration may also coexist (Cass et al. 1997; MacKenzie et al. 2001).

Clinical features

The majority of cases of CCAM are diagnosed by antenatal USS, usually at around 20 weeks' gestation. Most have a good prognosis, if not associated with the development of hydrops. The lesion may grow initially, reaching a maximum size at around 25 weeks' gestation (Kunisaki et al. 2007). About half of these regress, so that postnatal detection is not possible with either plain chest radiography or computed tomography (CT) scanning in approximately 60% of these (Cavoretto et al. 2008).

Hydrops occurs in a small number of cases and this is likely to be the result of raised central venous pressure due to vascular compression from the lesion. Oesophageal compression leading to reduced swallowing may cause polyhydramnios. This partly accounts for the increased risk of preterm birth, which has been noted in up to 50% of cases in some series, although the wide range for this may be reflective of differing approaches to antenatal intervention (Thorpe-Beeston and Nicolaides 1994; Miller et al. 1996; Duncombe et al. 2002).

Postnatal presentation is variable and ranges from absence of symptoms in up to 50% of cases (Neilson et al. 1991) to severe respiratory distress requiring artificial ventilation and other forms of respiratory support. Pneumothorax (Gardikis et al. 2002) and PPHN (Rescorla et al. 1990) have also been noted in association with CCAM in the early neonatal period. Late presentation in children and adults, most commonly with recurrent lower respiratory tract infection, is now unusual, owing to widespread routine antenatal USS (Lujan et al. 2002). However, some recently reported cases presenting from infancy to adulthood describe lung abscess (Dahabreh et al. 2000), pneumothorax (Lejeune et al. 1999), haemoptysis (Chen 1985) and incidental finding on a CXR (Avitabile et al. 1984).

A number of case reports suggest an association between CCAM and various intrathoracic neoplasms. Bronchoalveolar carcinoma has developed both in children as young as 11 years old as well as in adult patients (Granata et al. 1998). Pulmonary rhabdomyosarcoma has also been reported in a number of cases (Ozcan et al. 2001), the youngest being 13 months old. Bronchopulmonary blastoma may develop from CCAM and has been found after initial surgical resection (Papagiannopoulos et al. 2001).

Diagnosis

Antenatal USS may detect CCAM as early as 16 weeks' gestation, when the lesions appear as a hyperechogenic mass in microcystic

Fig. 27.51 (A) Frontal chest radiograph showing mixed increased density and subtle overinflation with lucency in the right mid- and lower zone. (B) Coronal computed tomography (CT) of chest (lung window settings), showing a multicystic lesion within the right lung. (C) Minimum-intensity projection (MIP) image of the CT dataset, demonstrating the extent of the lesion.

lesions or as larger cysts (Thorpe-Beeston and Nicolaides 1994). Serial ultrasound scans are recommended so that regression, progression and development of complications such as hydrops can be detected. Ultrasound estimation of the volume of CCAM has been used to predict the development of hydrops (Crombleholme et al. 2002), and Doppler blood flow waveforms of fetal pulmonary arteries have been found to predict pulmonary hypoplasia accurately (Fuks et al. 2003). More recently, fetal magnetic resonance imaging (MRI) has been evaluated and may be useful in distinguishing between CCAM and other anomalies such as CDH (Hubbard et al. 1999).

Initial postnatal imaging with plain CXR usually shows a cystic, solid or mixed lesion in the affected lobes, depending on the underlying type of CCAM. Mediastinal shift is common. Further evaluation with CT scanning is usually recommended in order to detect small lesions that may be difficult to visualise on a CXR (Fig. 27.51). This is important in order to establish that a lesion seen antenatally has completely involuted and to distinguish between CCAM and CDH, as well as to depict anatomical location accurately (Kim et al. 1997). The CT scan should be performed as early as possible in symptomatic cases or at a later stage within the first few weeks of life if there are no initial symptoms. Colour flow Doppler studies may be useful to exclude systemic arterial blood supply that has been noted in some cases of CCAM, although this may not be apparent until found during surgical resection (Cass et al. 1997).

Management

Termination of pregnancy may be considered in pregnancies with poor prognostic features such as bilateral CCAM, early hydrops or associated severe congenital anomalies (Thorpe-Beeston and

Nicolaides 1994; Lee et al. 1996; Golaszewski et al. 1998). Amniotic fluid reduction by amniocentesis may reduce the risk of preterm birth, although there is no direct evidence supporting this in cases of CCAM. If there is marked mediastinal shift associated with large fluid-filled cysts, thoracoamniotic shunting has led to high survival rates (Adzick et al. 1998; Crombleholme et al. 2002; Cavoretto et al. 2008) but such intervention is indicated only if there is polyhydramnios or hydrops (Dommergues et al. 1997). For massive multicystic or predominantly solid CCAM associated with hydrops, fetal lobectomy may provide an alternative therapeutic option. This was performed in 13 cases between 21 and 29 weeks' gestation, resulting in eight healthy survivors at 1–7 years' follow-up (Adzick et al. 1998).

Early postnatal surgical resection with lobectomy or segmentectomy is required in symptomatic cases. Mediastinal shift, pulmonary hypoplasia and pulmonary hypertension may be problematic in the initial postnatal period and high-frequency oscillatory ventilation (Waszak et al. 1999), inhaled nitric oxide (Banerjee et al. 2002), selective intubation of the contralateral lung (Castillo et al. 1994) and ECMO (Njinimbam et al. 1999) have been used to stabilise infants with CCAM perioperatively. The risk of recurrent infection and malignant change suggests that surgery should also be considered in asymptomatic cases, and is often recommended towards the end of the second year of life, allowing the baby to grow before the onset of symptoms, which are rare before this time in cases asymptomatic during the fetal and neonatal period (Sueyoshi et al. 2008).

Prognosis

Outcome is excellent in most cases of antenally diagnosed CCAM in the absence of hydrops, with approximately 95% survival to

hospital discharge (Cavoretto et al. 2008). Hydrops is associated with approximately 95% fetal or early neonatal mortality. Polyhydramnios, mediastinal shift, type 3 disease, presence of other congenital malformations and preterm birth are also associated with a worse outcome (Thorpe-Beeston and Nicolaides 1994; Miller et al. 1996).

Recurrence rates in partially resected CCAM are low (Mentzer et al. 1992).

Congenital lung cysts

Congenital lung cysts may be extrapulmonary (mostly arising from bronchi or trachea) or intrapulmonary (mostly arising from alveoli). They are usually single, confined to one lung and are not associated with cystic changes in other organs. The commonest site is in the carinal region, but they may occur at the periphery of the lung, below the diaphragm or in the mediastinum (Maier 1948).

Signs of respiratory distress due to congenital lung cysts are extremely unusual in the neonatal period, with only 10% diagnosed at this stage, a further 14% during the first year and over 50% in adults, many being discovered incidentally by routine CXR (Ribet et al. 1996). Symptoms and timing of presentation depend on the size and site of congenital lung cysts.

Diagnosis is usually from CXR appearance. CT, MRI or USS may be useful in differentiating large congenital lung cysts from CCAM and congenital lobar emphysema.

Surgical resection is recommended for all congenital lung cysts. More recently, thoroscopic surgical techniques have been described for these lesions (Rothenberg 2000).

Pulmonary sequestration

Pulmonary sequestration is a congenital abnormality consisting of intrathoracic or intra-abdominal lung tissue with arterial blood supply from the thoracic or abdominal aorta. There is usually no connection to the tracheobronchial tree. Traditionally, classification has been according to the position of the lesion, as intra- or extralobular, with intralobular lesions lying adjacent to normal lung tissue within the pleura and extralobular lesions being within their own pleura. Subsequently, a classification based on the airway connection, the arterial supply, venous drainage and lung parenchyma has been advocated (Clements and Warner 1987).

It was initially suggested that pulmonary sequestrations are likely to arise as a result of an accessory lung diverticulum from the primitive foregut, with extralobular lesions being more distal. A further explanation of aetiology is that of the haphazard branching theory, in which there are abnormal connections or malinosculations between the primitive foregut and aortic-pulmonary arch system (Lee et al. 2002).

Pathophysiology

Intralobular pulmonary sequestrations usually consist of a mass of airless alveoli, which may have a cystic appearance. They are usually left-sided and involve the lower zone in 85% of cases (Weinbaum et al. 1989). Arterial supply is directly from the aorta in most cases, with venous drainage into a pulmonary vein. Extralobular lesions may be intrathoracic or abdominal, and venous drainage is into systemic veins, usually the vena cava or azygous veins (Gamillscheg et al. 1996). One variation involves sequestration in the right lung with resultant right-lung hypoplasia, with infradiaphragmatic venous drainage to the vena cava from the sequestered lobe and surrounding otherwise normal lung. This is known as scimitar

syndrome, owing to the characteristic appearance of the CXR and angiogram (Gao et al. 1993).

Clinical features

Antenatal diagnosis may be by USS, showing an echogenic intrathoracic or intra-abdominal mass. Polyhydramnios is common and fetal pleural effusions and hydrops may also occur. More recently, fetal MRI has been used to obtain further detail (Dhingsa et al. 2003).

Intralobular lesions may lead to symptoms of respiratory distress in the neonatal period owing to compression of adjacent normal lung or heart failure due to a large arteriovenous shunt. However, up to 80% of babies may remain symptom-free initially but present later in childhood or adulthood with recurrent pulmonary infection, pleural effusion or haemoptysis. The diagnosis may be made on CXR as an incidental finding. Scimitar syndrome can present in the neonatal period with massive haemorrhage from the affected lung (Alvizatos et al. 1985).

Other congenital malformations are rarely found in intralobular pulmonary sequestration. However, in two series, more than 50% of pulmonary sequestrations were associated with type 2 CCAM (Conran et al. 1999; Bratu et al. 2001). These differed from those without CCAM, with earlier presentation, usually within the first 3 months of life.

Extralobular pulmonary sequestration often remains asymptomatic and is usually found incidentally. Other congenital malformations such as CDH and CHD occur in nearly 60% of cases (Savic et al. 1979).

Diagnosis

CXR shows pulmonary sequestration as a radiodensity, usually in the posteromedial part of the left lung. Doppler ultrasonography, spiral CT scanning or MR angiography may be used to determine arterial supply and venous drainage (Hang et al. 1996) (Fig. 44.13).

Management

Antenatal drainage of polyhydramnios and insertion of thoracoabdominal shunts for associated hydrothorax may improve outcome after antenatal presentation of pulmonary sequestration (Lopoo et al. 1999).

Early surgical resection by segmentectomy or lobectomy for intralobar sequestrations, and mass excision for extralobar sequestrations, have generally been recommended in order to alleviate the mass effect of large lesions and prevent other possible short-term complications such as haemorrhage and heart failure, as well as avoiding later infection (Becmeur et al. 1998; Halkic et al. 1998; Van Raemdonck et al. 2001). Successful minimally invasive surgery using thoracoscopy or laparoscopy has also been described (Mezzetti et al. 1996; Danielson and Sherman 2001).

Transumbilical arterial embolization has been reported, with some success and minimal complications. However, complete regression occurred in only 53% of cases (Lee et al. 2008).

Prognosis

Antenatal regression and resolution of pulmonary sequestration may occur in approximately 50% of cases (Becmeur et al. 1998). Polyhydramnios and hydrops are likely to be associated with a worse outcome. Postnatal regression has also been described but appears to occur less frequently (Garcia-Pena et al. 1998).

Surgical resection in the neonatal period or later generally leads to excellent results, with favourable long-term outcome (Halkic et al. 1998; Lopoo et al. 1999). Metaplasia or neoplastic change has not been noted from histological examination of resected pulmonary sequestrations.

Congenital pulmonary lymphangiectasis

Congenital pulmonary lymphangiectasis (CPL) is a rare condition in which there is cystic dilatation of the pulmonary lymphatics with obstruction to their drainage. It is usually bilateral and associated with severe respiratory failure, although unilateral and localised lesions have been described (Rettwitz-Volk et al. 1999). It is more common in males and may be associated with other abnormalities of the lymphatics. Noonan et al. (1970) described three groups of patients with CPL:

1. CPL associated with generalised lymphangiectasis. Presentation is often antenatal with hydrops. Generalised lymphangiectasis develops with malabsorption and hemihypertrophy.
2. CPL associated with CHD. Total anomalous venous drainage, hypoplastic left heart, pulmonary stenosis, and atrial and ventricular septal defects have all been described in association with CPL.
3. CPL as a primary developmental defect of the lung. This may occur in Noonan, Turner and Down syndrome.

Pathophysiology

CPL may arise as a result of failure of fusion of embryonic lymphatic channels, which initially develop as spaces within the lung bud. It has also been suggested that it may be part of a generalised developmental anomaly of lymphatics, rather than an intrinsic lung defect. Lymphatic obstruction results in large, firm and heavy lungs which are poorly expanded.

Clinical features

Presentation is usually antenatal, with hydrops or severe respiratory distress in a term infant. Exogenous surfactant therapy may lead to temporary resolution of respiratory failure.

Diagnosis

In generalised bilateral CPL, lung fields usually have a ground-glass appearance on CXR, but are usually well inflated or even over-inflated, and have prominent interstitial lymphatics radiating from the hilar areas. Chylous pleural infusions may be present. The diagnosis is only confirmed by lung biopsy.

Localised lesions may present with a cystic mass, which appears similar to a cystic adenomatoid malformation on antenatal USS or postnatal CXR (Rettwitz-Volk et al. 1999).

Management

Surgical excision may be possible for localised CPL (Rettwitz-Volk et al. 1999). Bilateral disease presenting with severe respiratory failure has a poor prognosis.

Pulmonary alveolar proteinosis (congenital alveolar proteinosis)

Pulmonary alveolar proteinosis (PAP) is a rare condition characterised by accumulation of lipoproteinaceous material in the alveolar space, which impedes gas exchange. Presentation is usually in older children and adults but severe neonatal respiratory failure has been described. Familial recurrence has been reported, suggesting autosomal recessive inheritance in some cases (Ball et al. 1995).

Pathology

The lipoproteinaceous material found distending the alveoli stains positive for periodic acid–Schiff and represents surfactant, which accumulates owing to defective alveolar macrophage function. Changes are usually generalised in the neonatal form of the disease, although a focal distribution has also been noted (Mildenberger et al. 2001). Histological evidence from some reported cases of PAP has suggested that the underlying aetiology is a congenital deficiency of surfactant protein B (SP-B) (Nogee et al. 1993). Several mutations in the SP-B gene have been described, with the 121ins2 mutation occurring in approximately two-thirds of cases (de Mello and Lin 2001). A mutation of the granulocyte–macrophage colony-stimulating factor/interleukin (IL)-3/IL-5 receptor common beta chain has also been reported (Dirksen et al. 1997).

Clinical features and diagnosis

Presentation is usually with severe, prolonged respiratory failure in a term infant. The CXR appearance is suggestive of surfactant deficiency, with diffuse ground-glass opacification of the lung fields. CT also shows generalised opacification, with prominent interlobular septa (Newman et al. 2001).

Diagnosis is confirmed by demonstration of decreased or absent SP-B by enzyme-linked immunosorbent assay in aspirates obtained by alveolar lavage or immunostaining of lung tissue from biopsy (Ball et al. 1995).

Management

Ventilatory support is required from birth in congenital alveolar proteinosis. Temporary improvement may result from alveolar lavage and exogenous surfactant therapy, but the condition is usually fatal within a few weeks (Ball et al. 1995). Long-term survival has only been reported after lung transplantation (Huddleston et al. 2002).

Congenital lobar emphysema

This is a rare condition in which the affected lobe is hyperinflated and therefore also referred to as congenital large hyperlucent lung. The incidence in babies has been estimated as 1 in 90 000, although it may present in older children and adults (Man et al. 1983; Critchley et al. 1995). Congenital lobar emphysema is more common in males (Karnak et al. 1999) and familial cases have been described, but with no common pattern of inheritance (Thompson et al. 2000; Roberts et al. 2002). CHD occurs in 10–15% of cases (Karnak et al. 1999).

Pathophysiology

The hyperinflated lobe or lobes occurs as a result of a 'ball-valve' mechanism for which a number of aetiologies have been

implicated. These include defects in bronchial cartilage, resulting in bronchomalacia (Doull *et al.* 1996), partial large-airway obstruction due to excessive mucus or inflammatory exudates (Thompson and Forfar 1958) and extraluminal compression of large airways by bronchogenic cysts (Gerami *et al.* 1969) or aberrant blood vessels (Raynor *et al.* 1967).

The affected lobe or lobes are distended and pale in colour, with absent ventilation and perfusion. Compression resulting in atelectasis of unaffected lobes occurs, along with mediastinal shift.

Clinical features

Presentation in the early neonatal period, with signs of respiratory distress, occurs in 50–60% of cases, with others being asymptomatic. Late presentation with recurrent lower respiratory tract infection is unusual (Karnak *et al.* 1999). On examination, the affected side may be hyperinflated, with reduced breath sounds, an increased percussion note and expiratory wheeze.

In case series, the left upper lobe was affected in 65% of cases, the right middle lobe in 24% and the right upper lobe in 11% (Senyuz *et al.* 1989; Dogan *et al.* 1997; Karnak *et al.* 1999; Thakral *et al.* 2001). One case series suggested that symptoms were worse when congenital lobar emphysema occurred in either upper lobe (Thakral *et al.* 2001).

Diagnosis

Antenatal diagnosis with USS and MRI has been reported in very few cases (Olutoye *et al.* 2000; Babu *et al.* 2001). Like other congenital lung lesions diagnosed on antenatal USS, some appear to decrease in size or even disappear altogether as the pregnancy progresses, but signs may still occur soon after birth.

Postnatally, most cases of congenital lobar emphysema can be diagnosed by a plain CXR, which typically shows hyperinflation of the affected lobe, mediastinal shift and compression of other parts of both lungs. Delayed resorption of lung fluid is commonly seen within the affected lobe as increased opacity. Ventilation perfusion scintigraphy, showing decreased ventilation and perfusion, and CT scans may also aid diagnosis (Stigers *et al.* 1992; Karnak *et al.* 1999). Echocardiography is necessary to exclude CHD, and barium swallow, bronchoscopy and cardiac catheterisation with angiography may be required to exclude a vascular ring (Roguin *et al.* 1980).

Management

Most cases of congenital lobar emphysema presenting with symptoms in the neonatal period require surgical lobectomy. Asymptomatic cases or those with minimal symptoms can usually be managed conservatively (Karnak *et al.* 1999). Successful treatment with flexible bronchoscopy (Phillippos and Libsekal 1998) and selective bronchial intubation has also been described in a small number of cases (Glenski *et al.* 1986).

Ciliary abnormalities

Primary ciliary dyskinesia (PCD), also known as the immotile cilia syndrome, is an autosomal recessive condition with an incidence of approximately 1 in 15 000.

Pathophysiology

PCD occurs most commonly due to absence of the dynein arms on the outer microtubular doublets (Afzelius 1976). Other abnormalities of ciliary ultrastructure, recognised by electron microscopy, have also been described, along with ciliary aplasia (Fonzi *et al.* 1982; Sturgess *et al.* 1986). Patients with typical symptoms and decreased ciliary beat frequency but normal ciliary ultrastructure have also been described (Greenstone *et al.* 1983).

Clinical features

Ciliary dysfunction leads to poor clearance of respiratory tract secretions, which predisposes patients to recurrent upper and lower respiratory tract infections, sinusitis and otitis media. Bronchiectasis may develop by mid- to late childhood or during adult life as a result of chronic respiratory infection. The incidence of dextrocardia and situs inversus (Kartagener syndrome) varies from 50% to 67% in large case series (Nadel *et al.* 1985; Coren *et al.* 2002). Male infertility is common, due to reduction of sperm motility or abnormal ciliary function in the vas deferens. There is also an increased risk of female infertility due to dyskinetic cilia in the fallopian tubes (Afzelius and Eliasson 1983).

Presentation in the neonatal period occurs in more than two-thirds of cases and may be with otherwise unexplained persistent signs of respiratory distress, pneumonia or mucoid nasal secretions (Whitelaw *et al.* 1981; Buchdahl *et al.* 1988). Diagnosis may also be suspected in cases of dextrocardia or with a positive family history.

Diagnosis

Diagnosis of PCD is established by analysis of a superficial brush biopsy sample of epithelial cells from the nasopharynx. This is examined under light microscopy to assess ciliary function. An electronic counting device or photometric methods are used to measure ciliary beat frequency, which is reduced in PCD. Electron microscopic examination is performed to assess specific structural defects of cilia. There is considerable genetic heterogeneity in PCD, therefore genetic testing is not carried out routinely (Blouin *et al.* 2000).

Management

Antibiotics for respiratory tract and other infections and chest physiotherapy may delay the onset of bronchiectasis. Surgical treatment for bronchiectasis is not normally required but lobectomy and successful lung transplantation have been reported in the most severe cases (Macchiarini *et al.* 1994). Successful intracytoplasmic sperm injection and in vitro fertilisation have been described in male patients (Cayan *et al.* 2001).

Prognosis

Bronchiectasis occurs in approximately one-third of cases by late childhood, but the severity is variable and prognosis is usually better than with cystic fibrosis or other causes of childhood bronchiectasis. Life expectancy can be normal but depends on the severity of bronchiectasis (Kollberg *et al.* 1978).

Part 6: Diaphragmatic hernia

Carmen Turowski Mark Davenport

Introduction

A number of diaphragmatic abnormalities may present with respiratory problems during infancy, the most common being a posterolateral congenital diaphragmatic hernia (CDH). This is usually associated with severe lung hypoplasia, and, despite many advances in its management, still has a high mortality. Anterior diaphragmatic hernias are smaller and tend to present later in infancy, often with gastrointestinal symptoms alone. Eventration of the diaphragm is a condition in which the cupola becomes thinned, stretched and

immobile but yet is still intact. Some degree of respiratory impairment is seen in most of these cases.

Congenital posterolateral diaphragmatic hernia

In 1848, the Czech anatomist Vincent [Bochdalek](#) described bowel herniation through the posterior part of the diaphragm, attributing it to the effects of an inverted fetus and rupture of the lumbocostal membrane. Although such posterolateral hernias are still widely

known by the eponym Bochdalek's hernia, he was certainly not the first to describe this type of diaphragmatic defect as detailed reports of CDH in both children (Holt 1701) and adults (Bonet 1679) had been published previously.

The embryological development of the diaphragm is complex: its mesenchyme is derived from the septum transversum and the dorsal mesentery of the oesophagus, and its muscular component from the innermost muscle layer of the thoracic cage and descending cervical myoblasts (Kluth et al. 1996). The nerve supply to this muscle is via the phrenic nerve (C3–5). There is a communication between the pleural and the peritoneal cavities (the pleuroperitoneal canal) up to the 8th week of gestation.

The orthodox hypothesis of the aetiology of CDH ascribes intestinal herniation to a failure to close the initially patent pleuroperitoneal canal. There is then visceral migration into the hemithorax and interference with the developing lung bud. This herniation would therefore occur during the late embryonic period at 8–10 weeks' gestation. More recent work has suggested that CDH occurs because of failure of normal apposition of the septum transversum and pleuroperitoneal folds (PPFs) arising from the posterior body wall between 6 and 10 weeks' gestation. PPFs are transient structures which form early in diaphragm development and are the target for migratory muscle precursor cells and the phrenic nerve (Clugston and Greer 2007).

There is an important alternative hypothesis which suggests that the primary defect is that of lung hypoplasia. Thus it has been suggested that the pleuroperitoneal canals are too small to accommodate even a single loop of bowel (Kluth et al. 1996) and that the diaphragmatic defect occurs in the posterior mesenchymal part of the nascent diaphragm rather than the pleuroperitoneal canal (Iritani 1984). Such studies also suggest that the defect therefore occurs earlier and equivalent to about 5 weeks' gestation, i.e. within the early embryonic period.

Most recent studies investigating causative factors in CDH have used animal models. These can be divided into surgically created diaphragmatic hernias in large animals (typically sheep) during the latter stages of gestation (Karamanoukian et al. 1995; Papadakis et al. 1998) and those resulting from exposure of small animals (typically rats and mice) to teratogens, such as the pesticide nitrofen, during the early stages of gestation (Iritani 1984; Leinwald et al. 2002).

In a typical CDH mouse model, it can be shown that nitrofen-exposed early embryonic lungs are both hypoplastic and developmentally immature before the presence of a diaphragmatic hernia (Leinwald et al. 2002). Various candidate gene defects (e.g. *HoxA4*, *TGF*, *N-myc*, *Slit*, *COUP-TFII*, *FOG2* and *GATA4m*) (Leinwald et al. 2002; Doi et al. 2009a, b) have been suggested as possible causes and there is a plausible hypothesis concerning inhibition of the retinoid signalling pathway. Thus, *COUP-TFII*, *FOG2* and *GATA4* genes are all regulated by the retinoid signalling pathway, and located on chromosomes 15q26, 8q23 and 8p23.1 respectively – regions reported to be deleted in some individuals with CDH (Doi et al. 2009b). Prenatal treatment with retinoic acid, an active metabolite of vitamin A, can upregulate pulmonary gene expression levels of *COUP-TFII*, *FOG2* and *GATA4* in the nitrofen model and prevent CDH formation. Other genes, such as *Slit-2* and *Slit-3*, may also have a role in pathogenesis as they seem to direct the functional organisation and differentiation of fetal lung mesenchyme and pulmonary bronchiolar development (Doi et al. 2009a).

Anatomy and pathophysiology (Fig. 27.52)

The diaphragmatic defect occurs in the posterolateral segment, although it may range from a simple muscular slit to complete

Fig. 27.52 Schematic illustration of the anatomy of congenital diaphragmatic hernia: posterolateral hernia of Bochdalek and anterior hernia of Morgagni.

agenesis. Left-sided hernias account for about 80% of most series (Charlton et al. 1991; Sweed and Puri 1993). Bilateral CDHs occur rarely and are associated with a much worse prognosis (Benjamin et al. 1988; Neville et al. 2003). In left-sided hernias, the hemithorax contains herniated bowel, stomach, spleen and often part of the left lobe of the liver. The herniated bowel is inevitably malrotated because of its abnormal development, although consequent duodenal obstruction is uncommon. A thin, almost translucent hernial sac occurs in about 20% of cases. Right-sided hernias usually contain the right lobe of the liver, and, because of its volume, this tends to plug the defect and may minimise herniation of other viscera.

Some degree of lung hypoplasia occurs with virtually all diaphragmatic hernias. This is most obvious on the ipsilateral side, where perhaps only a nubbin of tissue might remain, but is also seen on the contralateral side. Compared with normal term lungs, there is an absolute decrease in lung weight and volume and a decrease in compliance. The number of bronchial generations is reduced and true alveoli, which should start to be seen by 34 weeks' gestation, are uncommon. Most terminal air spaces are therefore still in the saccular phase of development. Along with an absolute decrease in lung tissue, there is a reduction in the total number of preacinar pulmonary vessels, although the ratio of capillaries per alveolus is retained. The pulmonary and intra-acinar arteries have an abnormally high smooth-muscle content, although it is unclear why this should be so. There is increased expression of endothelin-1 (ET-1), a potent vasoconstrictor, and its receptors (ET_A and ET_B) in such arterioles and this may be one molecular explanation for the frequency of persistent pulmonary hypertension of the newborn (PPHN) in CDH (Okazaki et al. 1998). There may also be changes in the developing cardiovascular system. For instance, the left ventricle and interventricular septum have been shown to be smaller both in CDH cases compared with age-matched human controls (Siebert et al. 1984) and in the experimental CDH lamb model (Karamanoukian et al. 1995). However, cardiac anomalies may

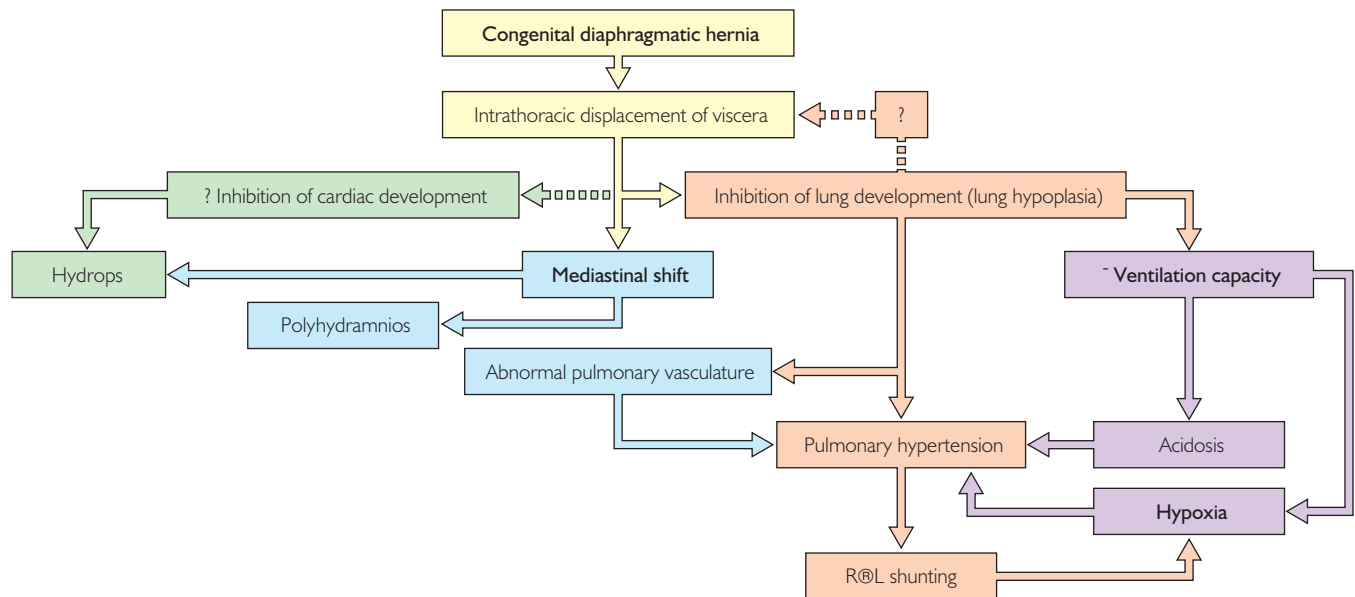

Fig. 27.53 Pathophysiology of congenital diaphragmatic hernia. Pulmonary hypertension, right–left shunting and hypoxia are the characteristic features of persistent pulmonary hypertension of the newborn.

simply be due to direct compression by herniated viscera, as right-sided hernias have been shown to cause diminution of the right rather than the left ventricle.

The pathophysiological sequence that explains some of the clinical features of a CDH is illustrated in [Figure 27.53](#). There is also an exaggerated response of the abnormally muscularised arterial resistance vessels to hypoxia, acidosis and hypercarbia, which causes in turn pulmonary hypertension and shunting of blood at several different levels from the right to the left side of the heart – PPHN.

Demography

The prevalence of CDH at birth has been estimated to be from 1 in 2000 to 1 in 5000, and does not appear to have any predilection for race or geographical area ([Wenstrom et al. 1991](#)). The sex ratio is equal, although right-sided defects may be more common in males ([Benjamin et al. 1988](#)). Although most CDHs are sporadic, with no known cause, there may be a genetic component in a small number, as there are reports of CDH in twins and families ([Crane 1979](#); [Mishalany and Gordo 1986](#)).

Associations

Although CDH was once thought of as an isolated anomaly, more accurate studies (including stillbirths and intrauterine deaths) and the advent of widespread prenatal ultrasound have shown this to be incorrect ([Adzick et al. 1985](#); [Benjamin et al. 1988](#); [Sharland et al. 1992](#); [Sweed and Puri 1993](#); [Harrison et al. 1994](#)). About 30–50% of diagnosed fetuses will have a further anomaly ([Sweed and Puri 1993](#)), although, because of intrauterine deaths, terminations and stillbirths, this falls to about 20–30% in live-born infants.

Various anomalies may be found, including chromosomal anomalies (e.g. Turner syndrome and trisomies 13, 18 and 21), major central nervous system malformations (e.g. anencephaly, neural tube defects) and most types of congenital cardiac defects (e.g. ventricular septal defect, aortic coarctation, tetralogy of Fallot, hypoplastic left heart and transposition of the great vessels) ([Benjamin et al. 1988](#); [Sweed and Puri 1993](#); [Harrison et al. 1994](#)). Similarly,

there is also a wide range of renal anomalies (e.g. agenesis and hydronephrosis) and, in males, undescended testes ([Benjamin et al. 1988](#)). Other anomalies less easy to classify include foregut duplication cysts and pulmonary sequestrations.

Fryns syndrome is characterised by a diaphragmatic hernia in an infant with an abnormal facies, distal limb anomalies, undescended testes in males and various gut and genitourinary anomalies ([Fryns et al. 1979](#)).

Clinical features

Antenatal ultrasound diagnosis of a diaphragmatic hernia has been possible for well over three decades now. The specific features include bowel loops, and liver or, more usually, stomach seen in the transverse four-chamber view within the thorax. Secondary features include mediastinal shift, hydrops fetalis and, most commonly, polyhydramnios. Right-sided defects are more difficult to diagnose, as the herniated fetal liver has a similar echogenicity to fetal lung.

The typical postnatal presentation is of increasing respiratory distress and cyanosis shortly after birth in a term infant. There are decreased breath sounds and air entry on the side of the hernia, with a shift of the trachea and cardiac impulse to the opposite side. The abdomen has a flat or even scaphoid appearance, as much of the viscera have already been displaced to the chest cavity.

A chest X-ray is diagnostic in most infants and will show air-filled loops of bowel within the hemithorax, often with severe mediastinal displacement ([Fig. 27.54](#)). Occasionally there may be confusion with the radiographic appearance of a cystic adenomatoid malformation of the lung, which may also present with respiratory distress. This can be distinguished on the plain film by noting the normal abdominal gas pattern and diaphragmatic integrity, or more accurately by introducing radiopaque contrast material into the stomach and proximal gastrointestinal tract ([Fig. 27.55](#)). An ultrasound scan can also differentiate these conditions. Occasionally, air does not enter the proximal bowel because of rapid intubation and resuscitation in the delivery room, especially if there has been an antenatal diagnosis. The usual radiographic appearance is then of

Fig. 27.54 Chest radiograph of infant at 1 hour of life, showing left diaphragmatic hernia, displacement of air-filled viscera into the hemithorax and a marked shift of mediastinum and heart.

Fig. 27.55 Chest radiograph of an infant with contrast medium in the stomach and small intestine, the latter lying within the left hemithorax.

Fig. 27.56 Chest radiograph of the early appearance of a diaphragmatic hernia, with a 'white-out' on the left side.

complete opacification on the side of the hernia – a 'white-out' (Fig. 27.56).

About 5% of infants with CDH will present beyond the first 24 hours of life, with failure to thrive, recurrent chest infections, a pleural effusion, or even as an incidental finding on chest X-ray.

Management

Antenatal

An increasing proportion of infants with CDH are diagnosed in utero by screening ultrasound during the second trimester. Amniocentesis should be offered on diagnosis – if a chromosomal anomaly is found, most obstetricians would recommend termination, as this is an invariably lethal combination.

It is important that these infants are delivered in regional centres where there are the necessary obstetric, neonatal intensive care and surgical facilities. In our centre, we tend to induce vaginal delivery at about 38 weeks' gestation to minimise the risks of unintended early labour and delivery in a peripheral unit.

Fetal intervention

A number of innovative antenatal techniques have been developed to try and influence the life-threatening lung hypoplasia only evident at the time of birth. The underlying theme of initial efforts was open fetal surgery during the second trimester to restore the

viscera to its correct abdominal habitus, repair the defect and allow the hypoplastic lung to self-correct during the remaining period of intrauterine life. The Fetal Medicine Center in San Francisco was a pioneer with this approach but ultimately admitted failure because of the high rates of intrauterine death and preterm labour and lack of real effect on lung growth (Harrison et al. 1993; Adzick and Harrison 1994). In one report of its experience between 1989 and 1991, 61 antenatally diagnosed fetuses were referred for consideration of surgery (Harrison et al. 1993). Second-trimester surgery was attempted in 14 fetuses. Of these, five died during the operation; a further three died in utero shortly after closure of the hysterotomy, and two were born prematurely but died. Only four survived to term and eventually to leave hospital.

A different and perhaps more elegant approach arose from the clinical observation that conditions causing congenital high-airways obstruction syndrome such as congenital laryngeal atresia resulted in lungs which were hyperplastic as fetal lungs are net fluid exporters, and obstruction caused intrabronchial hypertension and growth stimulation (Wigglesworth and Hislop 1987). In experimental animal models, tracheal occlusion replicated this and was associated with accelerated lung growth (Wilson et al. 1993; Bratu et al. 2001). In humans, the first attempts at this were relatively crude, involving open hysterotomy and tracheal clipping (Hedrick et al. 1994; Harrison et al. 2003). Latterly this has evolved into a true minimally invasive technique whereby, via a single port, a fetal tracheoscope is inserted and a detachable balloon located, inflated and then left in the fetal trachea (Papadakis et al. 1998; Harrison et al. 2003). The acronym FETO (fetal endoscopic tracheal occlusion) has been widely used for this intervention.

Currently, the technique is offered to high-risk fetuses (defined as having a 'liver-up' position and a lung-to-head ratio of ≤ 1.0) with an estimated survival without intervention of $<10\%$. The aim is to insert the tracheal balloon at 26–28 weeks' gestation with removal at about 34 weeks (Keller et al. 2004; Deprest et al. 2009). A number of methods of balloon removal are now used (e.g. ultrasound-guided puncture or fetoscopy) (Deprest et al. 2006, 2009; Sinha et al. 2009), although initially the technique of ex utero intrapartum treatment was needed to remove the balloon at the time of birth (Mychaliska et al. 1996). Although no maternal complications have been reported, iatrogenic preterm rupture of the membranes may still occur (Deprest et al. 2006).

This technique, without doubt, increases ipsilateral lung growth (Danzer et al. 2008) evident on serial ultrasonography and survival rates of $>50\%$ have now been reported (Deprest et al. 2009; Doi et al. 2009a; Sinha et al. 2009). It may not, however, alter more qualitative aspects of lung parenchyma or pulmonary arteriolar anomalies (Danzer et al. 2008). One possible side-effect of a fetal tracheal balloon is postnatal tracheomegaly, although its contribution to often complex symptoms remains to be elucidated (McHugh et al. 2009).

Medical

Infants with CDH presenting within 24 hours of birth are at considerable risk of death and should be endotracheally intubated, probably paralysed and ventilated. Prolonged attempts at bagging using a facemask can be dangerous and should be avoided, specifically because of the detrimental effects of intestinal distension. A large-bore nasogastric tube (e.g. 8 FG) should also be passed to decompress the stomach and small bowel. Neonatal resuscitation should then proceed on conventional lines.

Initially, the main problem is hypoventilation due to lung hypoplasia, and there will be a proportion of infants in whom this is so extreme as to be incompatible with life, and who will die

in the delivery room. Initial peak inflation pressures should be limited to 25 cmH₂O (to reduce barotrauma in small, stiff lungs), with rates of 60–80 per minute. Positive end-expiratory pressure is kept low to achieve maximum alveolar ventilation and achieve a preductal arterial saturation (SaO₂) of $>85\%$ with an acceptable degree of hypercarbia if necessary (PaCO₂ 45–60 mmHg and a pH of >7.3). This concept has been termed 'gentle ventilation' and the accompanying consequence 'permissive hypercapnea' and by reducing the risks of secondary barotrauma is felt to improve outcome.

In our institution, infants are paralysed (e.g. vecuronium 0.1–1.3 µg/kg/h) and have analgesia (e.g. fentanyl 2–8 µg/kg/h), although others argue that spontaneous breathing without relaxants may be preferable (Boloker et al. 2002).

Most infants will respond to medical measures and achieve acceptable blood gases. This has been described as the 'honeymoon' phase, as these infants can be deceptively well for a period before becoming increasingly unstable, often with severe hypoxic episodes, hypercarbia and an uncorrectable acidosis. The dominant pathophysiological problem in this phase is pulmonary hypertension and right-to-left shunting. Such PPHN can be diagnosed clinically by the typical rapid swings in oxygenation, and confirmed by measuring pre- and postductal arterial oxygen levels. Echocardiography during this period will show an enlarged right heart with pulmonary and tricuspid regurgitation and a right-to-left shunt at the foramen ovale and ductus arteriosus.

Newer ventilation techniques, such as high-frequency oscillatory ventilation and high-frequency jet ventilation, have been used in infants with diaphragmatic hernia and the former is used increasingly as a primary ventilation strategy permitting ventilation at lower mean airway pressures (e.g. no greater than 14–16 cmH₂O) (Reyes et al. 1998).

There is also a range of pharmacological agents which have been used to treat the PPHN associated with CDH, including tolazoline, prostacycline, prostaglandin E₁ (Shiyanagi et al. 2008), nitropruside, diltiazem (Islam et al. 1999) and nitric oxide (Kinsella et al. 1993; Finer et al. 1994). There is a functional surfactant deficit in infants with CDH, and some benefit had been shown from using first-breath exogenous surfactant in experimental models (Glick et al. 1992) and patients. However, a more recent review of 448 CDH infants treated with extracorporeal membrane oxygenation (ECMO) showed no advantage of additional exogenous surfactant (Colby et al. 2004).

Surgical

Nowadays there is no role for early (within 24 hours of birth) surgical repair. Abdominal replacement of the viscera and repair of the hernial defect cause a marked reduction in lung compliance and detrimental fluid shifts (Sakai et al. 1987), and should therefore be carried out only when the infant has achieved a period of cardiorespiratory stability (of at least 24 hours) with acceptable blood gases on conventional ventilation (e.g. F_iO₂ 0.5, P_O₂ 8 kPa (60 mmHg)) (Charlton et al. 1991).

European paediatric surgical centres during the early 1980s were the first to delay surgical repair (Cartlidge et al. 1986; Charlton et al. 1991), and this now seems to be the new orthodoxy (Lally et al. 1992; Nio et al. 1994). Nonetheless small randomised controlled clinical trials (Lally et al. 1992; de la Hunt et al. 1996) have not shown a clear survival advantage, probably because of the small numbers involved. During this period the largest single-centre experience with delayed surgery was reported from Manchester, where 86 high-risk infants had a survival rate of just over 70% (Charlton et al. 1991).

The surgical repair of CDH is performed through a subcostal incision. The displaced viscera are removed from the hemithorax and returned to the abdomen. A hernial sac, if found, should be excised to allow a tension-free musculoaponeurotic closure. The posterior margin of the defect may not be apparent initially and most have to be developed from the posterior abdominal wall. Primary closure is possible in about 75% of cases, but in those where this is impossible because of excessive tension or agenesis, other techniques have to be used. A patch of artificial material (e.g. GoreTex, Marlex, Permacol) remains the commonest strategy (Mitchell et al. 2008) but a muscle rotation flap (e.g. latissimus dorsi, internal oblique abdominis) can also be used to repair the defect (Bianchi et al. 1983). A chest tube left in the empty hemithorax is not necessary, and may be dangerous if used with suction, as the hypoplastic lung may overexpand and rupture. Abdominal wall closure can be problematic in a few infants owing to a small abdominal cavity and it is safer to insert a prosthetic patch to allow staged closure rather than risk compartment syndrome (Kyzer et al. 2004).

Minimally invasive repair of congenital diaphragmatic hernia

CDH repair can be accomplished using minimally invasive techniques, via either the abdomen or the chest, and this option has been increasingly available in larger centres. For instance, Gomes Ferreira et al. (2009) report a European multicentre series of 30 infants (down to 1.8 kg). Two-thirds were attempted thoracoscopically and overall about one-third were converted. Normally CO₂ is the gas used to create the pneumothorax and in these infants with long operating times and in the confined space of an infant's chest, hypercarbia can be an issue. The largest single-centre experience so far reported is from Oregon, USA, by Cho et al. (2009). Fifty-seven infants with CDH were reported, 29 of them having a thoracoscopic approach (one conversion). Postoperatively, although there were no significant differences in length of stay or postoperative mortality, there did seem to be an increased risk of hernial recurrence in the minimally invasive group (7% versus 20%). A theoretical problem with the thoracoscopic approach is that the reduction of the invariably malrotated bowel is left to chance, there being no opportunity of examining either the duodenum or the final position of the midgut. Nonetheless, it is likely that minimally invasive techniques will become a more widespread method of diaphragm repair, but pragmatically it should probably be reserved for the older more stable infant with better lung reserve.

The role of extracorporeal membrane oxygenation

ECMO is an option for infants with CDH if conventional methods of medical therapy are failing. The concept is simple: near-total cardiopulmonary support for a prolonged period of time (in practice, up to 10–14 days). ECMO was developed in the USA in the 1970s (Bartlett et al. 1977, 1985) and became available in the UK during the 1990s (albeit it is still restricted to supraregional centres). Early trials suggested benefit (Bartlett et al. 1985; O'Rourke et al. 1989a,b), but even in North America debate over its real role persisted (Azarow et al. 1997; Wilson et al. 1997; Congenital Diaphragmatic Hernia Study Group 1999) and there seems to have been a reduction in its application in CDH over time (Brown et al. 2009). The UK Collaborative ECMO Trial reported in 1996 failed to recruit enough infants in the CDH subgroup for the differences in survival to be statistically significant, but the only survivors were in the ECMO arm. The North American ECMO experience suggests that a survival rate of about 50% will be found in infants with CDH

(Guner et al. 2009), which is significantly worse than that achieved when ECMO is offered for other indications in neonates (e.g. meconium aspiration syndrome) (Heiss et al. 1989; Lally et al. 1992; UK Collaborative ECMO Trial Group 1996).

The indications, technique and morbidity associated with ECMO are fully discussed elsewhere (pp. 525–526). Surgical repair of the hernia may be performed while on ECMO but should probably be deferred until the infant has improved enough to be almost ready for decannulation and cessation of heparinisation (Wilson et al. 1994), if not following cessation itself.

Prediction of prognosis

It is logical to try and find specific or measurable features which will predict outcome in diaphragmatic hernia, because of the high mortality of this disease and the range of possible treatment options. A number of studies have assessed various factors as being of prognostic value, and can be divided into antenatal and postnatal.

Antenatal

Sebire et al. (1997) reported a difference in outcome of CDH detectable as early as 10–14 weeks' gestation, on the basis of the ultrasound-measured nuchal translucency, with higher values predicting a poor prognosis. It seems that the earlier the diagnosis is made antenatally, the worse the outcome. For instance, only 42% survived from a cohort of 83 fetuses with isolated CDH diagnosed before 24 weeks' gestation, compared with all of a cohort of 10 fetuses diagnosed after 24 weeks (Harrison et al. 1994). Polyhydramnios has also been a poor prognostic feature in some series (Albanese et al. 1998), although not in others (Sinha et al. 2009). The fetal stomach is found in the chest in most cases, but if it is found within the abdomen this seems to be a good prognostic feature. The position of the fetal liver seems to be important, with a significant (i.e. ultrasonically detectable) portion within the hemithorax having a poorer prognosis (Albanese et al. 1998; Sinha et al. 2009).

Various attempts have been made to estimate lung hypoplasia antenatally. Over the past decade this has been refined into the calculation of a single measurement – the lung-to-head ratio, where a ratio of ≤ 1 has an extremely poor prognosis (Lipshutz et al. 1997) and, by implication, requires antenatal intervention. In those centres able to offer FETO, then this, together with a 'liver-up' position, is the key criterion for its use (Deprest et al. 2006, 2009; Sinha et al. 2009). Nonetheless this is still a controversial area and far from being accepted universally (Yang et al. 2007).

Associated congenital cardiac anomalies are, of course, indicative of a poor outcome (Sweed and Puri 1993), but a number of groups have also looked at echocardiographic features of the fetal heart as a measure of lung hypoplasia or pulmonary vascular anomalies. UK investigators have suggested that both the ratio of left-to-right ventricular internal measurements (Crawford et al. 1989; Sharland et al. 1992) and the ratio of aortic-to-pulmonary artery diameters (Crawford et al. 1989) are valuable as prognostic features in isolated diaphragmatic hernias, both reflecting left ventricular underdevelopment.

Postnatal

For those infants who are not diagnosed antenatally, the age at presentation is important. The minority who present after 24 hours of life should have a survival prospect approaching 100%. Poor outcome is associated with early symptoms, prematurity and low birthweight.

Table 27.17 Derived predictive indices in congenital diaphragmatic hernia**Oxygenation index (OI)**

$$OI = \frac{\text{mean airway pressure (cmH}_2\text{O)} \times F_{IO} (\%)}{PaO_2 \text{ (KPa)}}$$

(NB: if PaO_2 is more familiar in mmHg then divide result by 7.5)

Ventilation index (VI)

$$VI = \text{respiratory rate (breaths/min)} \times \text{mean airway pressure (cmH}_2\text{O)}$$

Wilford Hall/Santa Rosa prediction formula

$$WHSR_{PF} = \text{highest } PO_2 - \text{highest } PCO_2$$

(N.B. measured on first day)

Achieving normal arterial blood gases is the final result of an effective pulmonary system, and the degree to which this is successful has been used as a prognostic factor. Initially, this is apparent clinically in the Apgar score, but is relatively crude. However, if a postductal $Paco_2$ of 5.5 kPa (40 mmHg) or a postductal PaO_2 of 13 kPa (100 mmHg) (Bohn et al. 1987; O'Rourke et al. 1989a,b) can be achieved with conventional ventilation, this suggests adequate lung tissue for survival. The degree of ventilatory support required to achieve such blood gases can also be incorporated into a variety of indices (Table 27.17), and of these the best is probably the oxygenation index (OI). In our series, the best OI (day 1) had a sensitivity (for good outcome) and specificity of 85% and 94% respectively (Sinha et al. 2009).

At present it is not possible to measure the critical lung mass in neonates directly, although there have been attempts to measure some indirect indices of lung function (e.g. compliance and functional residual capacity (FRC)) early in the postnatal period in these infants (Sakai et al. 1987; Dimitriou et al. 1995; Kavvadia et al. 1997). Such studies have shown that day 1 compliance rather than FRC has a predictive relationship to outcome. Serial studies showed that, in survivors, only compliance increased over the first 2 weeks, FRC remaining constant (Kavvadia et al. 1997). Of course, measurement of lung volumes remains confined to specialist centres, but there is even predictive value derived from the measured lung area on the postoperative chest X-ray (Dimitriou et al. 2000).

Echocardiography has been used to assess the degree of PPHN (Haugen et al. 1991; Hasegawa et al. 1994). Some echocardiographic variables (e.g. McGoon and pulmonary artery indices) may also have value when performed sequentially, to show the improvement in pulmonary vascular stability and, perhaps, the most appropriate physiological time for surgery (Takahashi et al. 2009).

The size of the diaphragm defect itself has been related to prognosis. Diaphragmatic agenesis (Lally et al. 1992) particularly, and all those where a patch is needed to repair the defect (West et al. 1992; Sinha et al. 2009), have been associated with a poorer outcome.

Outcome in congenital diaphragmatic hernia

No surgical series of diaphragmatic hernias has ever been able to emulate Robert Gross's first report of 100% survival in seven infants and children in 1946. This paradox is, of course, entirely due to preselection, as only the least affected infants used to survive to reach paediatric surgical centres. Table 27.18 illustrates recent survival statistics from a number of different centres throughout the world.

Recurrence may occur and indeed appears to be increasing in frequency in line with increased use of prosthetic patches, ECMO and increased survival of marginal infants (Moss et al. 2001; Fisher et al. 2009). The incidence varies but with assiduous follow-up and repeated chest X-rays may be identified in up to 20% of children (Nobuhara et al. 1996; Moss et al. 2001; Fisher et al. 2009). Recurrence can present with respiratory or gastrointestinal symptoms, and is usually confirmed on a chest X-ray. Surgical repair is advised in most.

Chest wall deformity can be obvious in some older children, and can manifest as pectus excavatum or scoliosis. It is presumed to be due to a reflection of underlying lung hypoplasia but untoward neodiaphragmatic tension may play a role. Consideration should be given to surgical correction, but is probably best deferred until adolescence.

Surviving infants have usually required a prolonged stay in intensive care, often with periods of hypoxia, hypercarbia and acidosis. Although early studies suggested that long-term complications in survivors were minimal, this was probably because of selection of a smaller but 'better quality' cohort. Currently, more marginal survival is possible and the incidence of long-term problems is higher (Mychaliska et al. 1996).

Pulmonary function

Dramatic changes occur in lung structure after surgical repair, although not immediately. Lung weight and volumes do increase measurably after about 3 weeks. Sakai et al. (1987) suggested that there was a decrease in compliance in the early postoperative period, although this has been disputed by later studies (Kavvadia et al. 1997), perhaps because of variation in the timing of surgery. Histologically there is an increase in the number of alveoli, and a decrease in muscularisation of the interacinar arteries, although there is no change in bronchiolar airway generation.

In one study of long-term symptoms in CDH survivors, at discharge 16% still required oxygen, 43% required diuretics and 17% required regular bronchodilator therapy, rising to about 50% with a transient need during the first year (Muratore et al. 2001). The radiographic appearance of the chest returns to normal in most, although there are persisting anomalies in tested lung function (typically forced expiratory volume in 1 second and forced vital capacity) (Muratore et al. 2001). The progressive improvement in ventilation can be assessed using ventilation-perfusion scans, and such studies show specifically a long-term persistence of ipsilateral perfusion defects (Jeandot et al. 1989).

Gastrointestinal function

The principal gastrointestinal problem is one of acid reflux caused by distortion of the gastro-oesophageal junction and crura; this may occur in up to 50% of survivors (Kamiyama et al. 2002). This may be manifest by vomiting and feeding difficulties, and can prolong respiratory morbidity, presumably due to recurrent aspiration. Twenty-four-hour intraoesophageal pH measurement should be performed in all survivors where reflux is thought possible. Intensive medical treatment (e.g. antacids, H_2 receptor blockers, proton pump blockers and prokinetic agents) should be tried, although, because of the anatomical basis for reflux, surgical correction (e.g. a Nissen antireflux procedure) may be necessary.

Neurological

There is a long-term worry of neurological impairment in survivors, which is presumed to be due to neonatal hypoxia and periods

Table 27.18 Surgical outcome in infants with high-risk congenital diaphragmatic hernia

SERIES	N	PERIOD	TREATMENT	SURVIVAL (%)
Heiss et al. (1989) (Ann Arbor, USA)	16 34	1974–1981 1982–1987	– ECMO	50 76
Charlton et al. (1991) (Manchester, UK)	56 86	1976–1983 1983–1989	Immediate repair Delayed repair	55 71
West et al. (1992) (Indianapolis, USA)	65 46	1975–1987 1987–1992	– ECMO and delayed repair	43 67
Skari et al. (2002) (Scandinavian Multicentre)	157	1995–1998	Delayed repair and ECMO	65
Congenital Diaphragmatic Hernia Study Group (1999) (USA multicentre)	632	1995–1997	ECMO	53 (with ECMO) 77 (no ECMO)
Boloker et al. (2002) (New York, USA)	120	1992–2000	Delayed repair, ECMO (13%), 'gentle ventilation'	76 overall (62 with ECMO)
Jaillard et al. (2003) (Lille, France)	85	1991–1998	ECMO (30%)	60 overall
Migliazza et al. (2007) (Bergamo, Italy)	111	1994–2005	Delayed repair, HFOV, 'gentle ventilation'	70 overall
Yang et al. (2007) (San Francisco, USA)	107	1995–2004	Delayed repair, ECMO (fetal medicine centre)	59
Sinha et al. (2009) (London, UK)	86	1994–2007	Delayed repair (fetal medicine centre)	52 (FETO) 64 (non-FETO)
ECMO, extracorporeal membrane oxygenation; HFOV, high-frequency oscillatory ventilation; FETO, fetal endoscopic tracheal occlusion.				

of cardiovascular instability. One UK study of selected high-risk long-term survivors found a major neurological handicap in two of 23 children, although there was no clear relationship between poor outcome and measured indices of hypoxia and acidosis during the neonatal period (Davenport et al. 1992). Sensorineural hearing loss has been recently described in up to 50% of CDH survivors, although why is not really known (Morini et al. 2008). Certainly, potential audiototoxic drugs, including pancuronium, aminoglycosides and furosemide, are used during their neonatal care. Neurological follow-up in ECMO survivors is described on pages 525–526.

Anterior diaphragmatic hernias

The Italian anatomist Giovanni Battista Morgagni first described a hernia occurring between the costal and the sternal muscle origins of the diaphragm in a series published in 1769. There is usually a hernial sac, and over 90% occur on the right side (Fig. 27.57). Compared with posterolateral defects, there is seldom any associated lung hypoplasia, and, consequently, symptoms are mild. There may be other anomalies in a minority of cases, including extralobar lung sequestrations and congenital cardiac defects. Morgagni hernias have also been described in Down syndrome (Iritani 1984).

Most of the clinical features are due to incarceration of part of the bowel (commonly the transverse colon) and include vomiting, failure to thrive and intestinal obstruction. Some may be found incidentally on chest X-ray. Surgical repair is performed through an

Fig. 27.57 Lateral chest radiograph of an infant who presented with intermittent vomiting, showing an anterior Morgagni hernia.

upper abdominal approach and is usually straightforward. Trans-abdominal laparoscopic repair is also feasible and safe (Ponsky et al. 2002).

The pentalogy of Cantrell is a syndrome of an anterior diaphragmatic defect with pericardial defects, a short sternum, exomphalos and major intracardiac anomalies (Cantrell et al. 1958). While the full-blown pentalogy is rare, incomplete manifestations may not be and this syndrome should be suspected in infants where the exomphalos defect is sited higher on the body wall than usual. Van Hoorn et al. (2008) reviewed the literature between 1987 and 2007 and identified 58 examples of pentalogy of Cantrell, of which 37 died or were terminated in utero, illustrating its poor prognosis. The defect differs anatomically from a Morgagni hernia (right or left of xiphisternum), in being a symmetrical central defect exposing the heart, and this has been attributed to a defective formation of the septum transversum.

Diaphragmatic eventration

Eventration can be congenital or acquired. Congenital absence of anterior horn cells may be responsible (Werdnig-Hoffmann disease), with others being due to intrauterine infection (e.g. rubella, cytomegalovirus) or as part of a more generalised

chromosomal anomaly (e.g. trisomies 13–15 or 18). These anomalies are usually left-sided and may even be bilateral (Rodgers and Hawks 1986). Diaphragmatic denervation due to phrenic nerve injury may be related to birth injury (when it is often associated with brachial plexus injury) or thoracic surgery (e.g. patent ductus arteriosus ligation).

Eventration may be asymptomatic, but most present in infancy with respiratory distress, recurrent chest infections or bronchiectasis. Paradoxical movement of the hemidiaphragm causes mediastinal shift, basal atelectasis and futile movement of air from the ipsilateral to the contralateral lung.

Chest X-ray (posteroanterior and lateral views) and fluoroscopic screening should establish the diagnosis, and radionuclide ventilation scans may allow assessment of the degree of ventilatory impairment. The management of eventration depends on the symptoms: if asymptomatic, an expectant course should be pursued; if there is respiratory distress, however, a more aggressive approach should be followed. Positive-pressure endotracheal ventilation overcomes any immediate problems, and once the infant is stable he or she should undergo definitive surgical correction. This is achieved by radial plication of the diaphragm, approached from either the chest or abdomen. The taut plicated diaphragm increases breathing capacity and tidal volume, allowing safe ventilator weaning.

Part 7: Airway problems

Gavin Morrison

Introduction

Continuing advances in neonatology present the paediatric otolaryngologist with an increasing range of baby and infant airway problems. This chapter attempts to review the causes, investigations and management of the compromised airway from the specialist paediatric airway surgeon's viewpoint. Investigation, management and prognosis are discussed. Although this chapter is entitled Pulmonary disease of the newborn, airway obstruction in the newborn can involve any site from the nostrils to the alveoli. Higher upper airway obstruction (UAO), from the nose downwards, is therefore discussed, in addition to laryngotracheobronchial airway disease.

Tracheostomy, at one time the mainstay surgical procedure for airway obstruction, has seen changing trends over the years. Immunisation programmes against diphtheria, polio and *Haemophilus influenzae* (acute epiglottitis) have dramatically reduced infective indications. The increased survival of very-low-birthweight (VLBW) babies and babies with multiple congenital abnormalities has led to a continued need for long-term tracheostomy in some infants and children. There is significant morbidity and mortality associated with tracheostomy, and newer developments now facilitate a trend away from tracheostomy, even for severe airway obstruction. Congenital and acquired subglottic stenosis (SGS) can often be successfully treated by single-stage laryngotracheal reconstruction (SS-LTR), thereby avoiding tracheostomy. The ex utero intrapartum treatment (EXIT) procedure can also now be used in difficult cases with antenatally diagnosed airway obstruction. This part looks at the assessment and management of the range of airway problems from a practical viewpoint.

Development of the nose, larynx and trachea and lungs

At 4 weeks, a median laryngotracheal groove appears in the ventral wall of the developing primitive pharynx. This groove deepens and its edges fuse to create a tube, the laryngotracheal tube. At the cranial end of this tube, the lips do not fuse, remaining open into the pharynx with a slit-like aperture. This cranial end forms the larynx, the trachea lies below this and caudally two lung buds arise and grow outward, forming the bronchi and bronchioles. The laryngotracheal tube is lined with endoderm, which becomes the respiratory epithelium. The epiglottis arises from the hypobranchial eminence at the tongue base and two arytenoid swellings appear, one on each side of the laryngotracheal groove. These develop from 6 weeks, into the epiglottis and arytenoids, creating a T-shaped laryngeal cleft. Soon after its formation, the epithelial walls of this cleft adhere to each other, and the aperture of the larynx remains occluded until the third month, when the lumen reappears. With further growth, this new definitive aperture forms above the initial primitive one and the detailed features of the larynx are created. The thyroid cartilage is developed from the ventral ends of the fourth and/or fifth branchial arches and appears as two lateral plates, while the cricoid cartilage develops from two sixth-arch cartilaginous centres, which fuse ventrally and gradually extend and fuse on the dorsal side as well.

The right and left lung buds commence before the laryngotracheal groove becomes a tube and develop out into the pleural

passages. The lungs migrate caudally and at birth the bifurcation of the trachea (carina) is at the level of the fourth thoracic vertebra.

The primitive foregut is in continuity with the pharynx and elongates to form the oesophagus. The continuity between the oesophagus and the laryngotracheal groove is not maintained and the separation between these structures proceeds cranially to achieve complete separation of the lung buds and trachea from the oesophagus (Fig. 27.58).

Laryngeal webs result from incomplete separation of the arytenoid regions. Laryngeal clefts are posteriorly sited and can result in notching of the posterior cricoid or complete failure of fusion of this ring. Incomplete fusion of the tracheo-oesophageal wall can result in a laryngeal cleft superiorly and a tracheo-oesophageal fistula (TOF) more inferiorly. Congenital anomalies of the larynx and trachea are rare, estimated at between 1 in 10000 and 1 in 50000 (Van der Broek and Brinkman 1979). Laryngeal atresia results from failure of canalisation of the cricoid and/or separation of the arytenoids. If there is failure of development of the tracheo-oesophageal groove, then the lungs may arise from a common oesophagus or type 4 laryngeal cleft. Such infants can occasionally be resuscitated with oesophageal ventilation, but most will not survive the immediate neonatal period.

Higher upper airway obstruction

Choanal atresia

One in 7000 babies are born with choanal atresia (Lazar and Younis 1995). It can be unilateral or bilateral. This congenital anomaly occurs where there has been failure of the opening at the back of the nose. The obstruction can be membranous or bony and membranous. It is most common to find a bony stenosis with a thin central bony atretic plate or membranous closure.

Choanal atresia can occur as an isolated anomaly or as part of the CHARGE syndrome (coloboma of the eye, heart defects, atresia of the nasal choanae, retardation of growth and/or development, genital and/or urinary abnormalities and ear abnormalities and deafness) (Samadi et al. 2003). It is also sometimes found in association with other craniofacial conditions such as Treacher Collins syndrome. The atresia can be unilateral or bilateral in any of these conditions.

Fig. 27.58 The development of the trachea, bronchi and oesophagus.

Diagnosis and management

The diagnosis of unilateral choanal atresia may only become apparent when it proves impossible to pass a fine flexible catheter through each nostril into the pharynx, and there is a lack of mirror misting at the anterior nares. There is frequently no clinical airway obstruction, or just snuffly breathing. The diagnosis may therefore be delayed until later childhood. Bilateral choanal atresia, however, presents at birth, with severe UAO. This will usually require either intubation and ventilation, or maintenance of the upper airway by placing a Guedel airway orally, securely taped to prevent displacement, prior to definitive correction. Frequent oropharyngeal suctioning will then be required.

A high-resolution computed tomography (CT) scan in the axial plane, with bone and soft-tissue windows, should be undertaken. It is important for the paediatrician to attend the scan in order to decongest the nose with a few 0.5% ephedrine nose drops and then nasal suctioning to remove mucus immediately prior to imaging. Otherwise, mucus can be interpreted radiologically as a membranous atresia.

Surgery and postoperative care

Surgical correction of bilateral choanal atresia should be undertaken as soon as this is practicable, usually within the first 14 days of life. Unilateral atresia, unless there is unusually severe airway obstruction, is better corrected electively at any time from 6 months of age or even as a toddler. The surgical outcome will tend to be better in an older child. Either a transnasal or a transpalatal surgical approach is adopted. The bony atresia is drilled away under endoscopic control, and many surgeons then insert nasal stents fashioned from endotracheal tubing. These nasal tubes need to be kept clear by regular suctioning and irrigation with a few drops of saline or bicarbonate solution, as required. The baby's parent or carer should be taught this process prior to discharge home. The nasal stents are usually removed after 2–6 weeks and subsequent anaesthetics for endoscopic examination, dilatation and sometimes laser treatments are required. If stenting is not employed then steroid nose drops are used and early serial endoscopies are required in the first month after initial choanal correction. There is a relatively high incidence of restenosis following this surgery, regardless of the technique employed. Samadi et al. (2003) reported that about five surgical procedures were required to achieve maintained patency. Holland and McGuirt (2001) report improved outcomes using topical mitomycin C application at the time of surgery.

Oropharyngeal airway obstruction and stertor

Stertor describes the low-tone breathing noise resulting from turbulent airflow in an obstructed pharynx. It is almost a snoring, and typically arises from the level of the tonsils, adenoids or tongue base. It is usually quite easily distinguishable from the higher pitched, almost musical, wheezy quality of stridor, which signifies airway obstruction at the laryngeal level or below. There will often be associated chest recession with stertor or stridor.

In the neonate, stertor is unlikely to be caused by obstructive adenoid or tonsillar tissue which has yet to hypertrophy, but it will be seen in any condition in which there are rattly oropharyngeal secretions, or with altered muscular tone in the pharynx, associated with neurological disorders, and where the tongue base and epiglottic morphology is unusual or hypotonic, causing these structures to prolapse over the laryngeal opening on attempted respiration

Table 27.19 Causes of high upper airway obstruction

Nasal agenesis
Congenital nasal septal deflection
Nasal tumour (e.g. meningomyelocele)
Choanal stenosis
Choanal atresia
Craniofacial syndromes with midface hypoplasia
Macroglossia
Oropharyngeal lymphangioma or haemangiomata
Micrognathia (e.g. Pierre Robin sequence)
Glossoptosis, prolapsing tongue base
Abnormally high or posterior larynx
Vallecular or supraglottic cysts
Pharyngeal hypotonia (neurological disease)
Excessive oropharyngeal secretions
Foreign bodies
Adenotonsillar hypertrophy

(glossoptosis). Pharyngeal UAO and stertor are common in infants with congenital abnormalities of the region, such as Treacher Collins syndrome, Pierre Robin sequence and in other conditions with an associated cleft palate. It will be seen with macroglossia (e.g. Beckwith–Wiedemann syndrome). Other common conditions include lymphangioma (cystic hygroma) involving the tongue, pharynx and neck.

Progressive UAO in the infant may indicate an enlarging mucus retention cyst, usually found in the vallecula, at the tongue base. It may be seen on a soft-tissue lateral X-ray of the neck and should be diagnosed at endoscopic laryngoscopy. Undiagnosed, this simple condition can be fatal. It requires drainage and excision or marsupialisation. Table 27.19 lists the causes of high UAO.

Management of oropharyngeal upper airway obstruction

Clinical assessment remains important, checking the patency of both nostrils, examining the oral cavity and oropharynx and studying the baby for dysmorphic features. The degree of stertor, recession and the pulse oximetry monitoring will give a good indication of the severity. A lateral soft-tissue X-ray of the neck can be helpful. Referral to a paediatric ear, nose and throat (ENT) surgeon should be made.

Initial treatment, with general supportive measures such as oxygen and perhaps humidification, will be helpful. Even inhaled or nebulised mixtures of helium and oxygen (heliox, BOC Medical) can be considered. Continuous positive airway pressure (CPAP) delivered by nasal oxygen cannulae may stent the upper airway open and avoid the need for intubation. Sometimes the airway can be maintained by the insertion of a unilateral nasopharyngeal airway (prong), which will bypass the airway obstruction and can also allow better delivery of CPAP, if required. The presence of the prong, however, stimulates increased secretions and causes feeding difficulty; regular suctioning will be required.

Where there is a removable obstructive cause, such as enlarged adenoids or tonsils or a retention cyst, ENT surgery will be corrective. Cystic hygroma in the airway may be reduced in a number of ways, such as surgical debulking, laser treatments or sclerosing agents (OK-432 or doxycycline) (Molitch et al. 1995; Wimmershoff et al. 2000; Giguere et al. 2002). If pharyngeal airway surgery and/or supportive measures are not successful in the long term, then tracheostomy surgery becomes indicated. Many causes of congenital

UAO will slowly self-correct with growth, over a number of years, and allow much later decannulation of the tracheostomy.

Where the posterior tongue is bulky and prolapses, compressing the laryngeal inlet (glossoptosis), it may occasionally be possible to perform a posterior third midline wedge resection and lead to airway improvement. Maxillofacial techniques such as mandibular distraction surgery can also have a place in promoting earlier correction of the obstructed upper airway in association with the micrognathic mandible and even the hypoplastic midface in toddlers or children with craniofacial syndromes.

Prognosis of high upper airway obstruction

Acute inflammatory conditions associated with airway obstruction and surgically correctable conditions will hold a good prognosis. The baby requiring a tracheostomy because of congenitally compromised upper airway anatomy, however, may require a tracheostomy for 18 months to 4 years of life, before there has been adequate resolution with growth.

Laryngotracheal airway obstruction

Assessment of airway obstruction and stridor

Stridor, a high-pitched audible noisy breathing, indicates airway obstruction within the larynx, trachea or bronchi. The history may help to diagnose the cause and localise the obstruction. Inspiratory stridor frequently arises from the supraglottis or the vocal cords. Laryngomalacia is the most common cause. Biphasic stridor usually indicates a vocal cord, or subglottic, level of obstruction. A biphasic vocalisation noise is often found to be caused by bilateral congenital vocal cord paralysis in the newborn. Expiratory stridor progressing to wheeze indicates lower tracheal or bronchial obstruction. Exacerbating features and whether the stridor is constant or progressive can be helpful. If the cry is absent or abnormal, there may be a congenital laryngeal lesion (e.g. web); a unilateral vocal cord paralysis can give a husky cry. An associated cough may indicate laryngitis and subglottic inflammation with laryngotracheobronchitis (LTB) or croup, while a harsh or barking cough is seen with tracheomalacia.

Stridor is frequently exacerbated by feeding. Stridor from laryngomalacia is often seen when the baby is asleep and lying supine. Stridor that is exacerbated by increased activity or upset tends to indicate a fixed, narrowed airway such as SGS.

Babies can adapt to slowly developing subglottic or tracheal stenosis, resulting in a prolonged expiratory phase which reduces recession and stridor, masking the severity of the obstruction. Acute-onset airway obstruction, in contrast, will tend to produce much more marked signs of obstruction, with tracheal tug, subcostal and intercostal recession, use of accessory respiratory muscles, increased respiratory rate and sweating. It is noteworthy, however, that recession is not specifically a sign of airway obstruction, but of airway effort, and is therefore also seen in babies with respiratory distress in the absence of significant obstruction (p. 476).

Auscultation of the stridor over the sternum is helpful, especially in a noisy ward, and can give a good indication of the volume of airflow and severity of the obstruction.

The small newborn baby, even with airway obstruction, may initially show relatively little stridor, perhaps because of the small-volume, lower speed airflow. With increasing age, stridor will tend to become more marked. Laryngomalacia, for example, will often develop only after the first few weeks of life, or even later.

The overall assessment of the baby with stridor should include oropharyngeal and chest examination and attention to the rest of

the history, including an assessment of likely neurological and cardiac status.

Pulse oximetry readings and capillary blood gases, taken in the context of other associated conditions, will be helpful. To rely solely on a pulse oximeter can be misleading. Clinical evaluation of the baby remains important.

Investigations for stridor

Investigation of the baby or infant with stridor should include a chest X-ray (CXR). A lateral X-ray of the neck may yield helpful information. Some institutions undertake the so-called Cincinnati view – a coned high-kilovolt anteroposterior X-ray of the mediastinum, which can delineate the trachea and main bronchi. A barium swallow may demonstrate an abnormal swallowing reflex, aspiration or TOF, as well as compression from a vascular ring or sling. A pH study, CT scan and magnetic resonance imaging (MRI) scans, as well as an echocardiogram of the great vessels, are all additional investigations.

Investigations should be tailored to the individual baby, but the minimum investigations for a baby with stridor should include a CXR and referral to the paediatric ENT airway surgeons for diagnostic endoscopy.

Management of stridor and laryngotracheal airway obstruction

Universal supportive measures can be applied. Oxygen, humidification and nebulisers or even heliox may be helpful. Adrenaline nebuliser (1 ml of 1:1000 adrenaline mixed with 2 ml of normal saline) can be administered every few hours to most babies. Nebulised steroids may be helpful (Durward et al. 1998), and salbutamol is worth trying. Systemic steroids such as dexamethasone will reduce any acute inflammation, oedema or haemangioma. When there is respiratory failure despite these measures, CPAP or intubation and ventilation will be required.

Airway endoscopy

While the supportive measures and investigations described are helpful, almost all babies and infants with stridor and airway obstruction require endoscopy to confirm a diagnosis and, if possible, to treat the condition endoscopically. Flexible laryngoscopy with a 2–4-mm diameter flexible rhinolaryngoscope (passed through the baby's mouth whilst awake on the ward) may allow a diagnosis of a supraglottic obstruction such as a vallecular cyst or laryngomalacia and might confirm vocal cord lesions or paralysis. The subglottic airway will not be readily assessed with a flexible endoscope. If the baby is intubated, the more distal tracheobronchial tree can be visualised with a very fine flexible fiberoptic endoscope passed down the endotracheal tube (ETT). Flexible endoscopes therefore have an increasing diagnostic role in the neonatal unit, but do not allow as accurate an assessment as rigid microlaryngoscopy and bronchoscopy (MLB) and generally do not allow correction of the problem (therapeutic endoscopy).

A formal MLB in the operating theatre, under light spontaneous respiration general anaesthesia, will allow full assessment of airway obstruction and the possibility of endoscopic therapeutic procedures. The technique requires no neuromuscular blockade and only minimal sedation, so that spontaneous respiration allows a dynamic endoscopic assessment of the entire airway without the presence of an ETT. Oxygen and inhalational agents, such as isoflurane, can be

delivered through a nasal prong. The technique relies heavily upon the use of lidocaine spray to the larynx (7 mg/kg stat). Intravenous anaesthesia such as propofol is also employed. Views are obtained using the microscope and/or rigid endoscopes. Storz ventilating bronchoscopes allow ventilation when assessing the tracheobronchial tree, if needed. These techniques allow coaxial instrumentation and laser treatments.

Care of the intubated baby

Airway obstruction and prematurity require babies to be intubated with speed and skill. Many factors appear to be associated with endotracheal airway damage leading to acquired SGS. Choice of an appropriately sized tube, movement, infection (Suzumura *et al.* 2000), the length of time intubated and the number of reintubations are all factors. Downing and Kilbride (1995) reported that variables more commonly found in patients with SGS included greater number of intubations, use of an inappropriately large ETT and longer durations of intubation. Contencin and Narcy (1993) believe the size of the ETT to be a major risk factor for acquired laryngotracheal stenosis in the neonate, recommending use of a size 2.5 ETT in babies under 2500 g weight. Supraglottic laryngeal damage from intubation, which will increase the likelihood of failed extubation, is significantly more common in active neonates than in those who are relatively immobile (Albert *et al.* 1990). Pashley (1982) reviewed the risk factors and predictors of SGS, proposing a figure of the number of intubations \times the number of days intubated \times the number of days ventilated. A child with a risk factor figure of greater than 3000 was at high risk.

A small leak past the ETT is desirable. A tube smaller than size 3.0 will be more difficult to manage regarding patency and ventilation. Table 27.20 gives a guide to the expected diameter of the subglottis and trachea for age with appropriate endotracheal and tracheostomy tube sizes.

Tube design may be another important feature. The Cole shouldered tube provides easier and safer intubation because of the rigidity of the fatter oropharyngeal component, but positioning is important as the shoulder can prolapse through the glottis, and its increased diameter will then cause trauma or even malacia (Brewis *et al.* 1999). Tube fixation techniques and the preferences for oral

or nasal intubation remain debated. There is no strong evidence to support any particular method.

There is a strong clinical suspicion that an intubated baby who is very active and mobile is at greatly increased risk of developing glottic laryngeal granulations and subglottic ulceration, leading to failed extubation and stenosis. There is a difficult balance to be struck in the very immature baby (who often requires ventilation for several weeks) between the desire to avoid too much movement of the ETT and the need for 'developmental care' and periods of interaction with carers and parents (Ch. 4). Occult or overt acid reflux is considered to be a detrimental factor in laryngeal and subglottic trauma, leading to failed extubation.

Deep suctioning through an ETT will also cause mechanical trauma with ulcerations and granulations. Suction techniques should involve introducing the suction tip just beyond the end of the ETT and then applying the suction with rotation and a gradual withdrawal (Fig. 27.59).

Extubation

For the baby deemed fit for a trial of extubation, different weaning protocols have been studied. Randolph *et al.* (2002) found extubation failure rates are not significantly different from one another. Barrington *et al.* (2001) showed that nasal synchronised intermittent mandatory ventilation was effective in preventing extubation failure compared with CPAP. The use of respiratory stimulants such as doxapram or methylxanthines to facilitate successful extubation has been studied, with mixed results. Most neonatal units use caffeine prior to extubation in babies of less than 32 weeks' gestation (p. 529).

When there is initial failure of extubation, and an airway-obstructive cause seems probable, then reintubation for 48 hours with heavy sedation to reduce tube movement and the use of systemic steroids as well as ranitidine or a proton-pump inhibitor may allow subsequent successful extubation.

Failed extubation

Where there is repeated failure of extubation, referral should be made to a paediatric ENT surgeon. These babies tend to fall into

Table 27.20 Approximate neonatal and infant airway parameters

	PRE-30 WEEKS	30 WEEKS TO TERM	1 MONTH	6 MONTHS	12 MONTHS
Expected cricoid AP diameter	3.6 mm	4.4 mm	5.0 mm	5.8 mm	6.2 mm
Appropriate Portex blue line ETT size	2.5 (OD 3.4 mm)	3.0 (OD 4.3 mm)	3.0 (OD 4.3 mm)	3.5 (OD 4.8 mm)	4.0 (OD 5.4 mm)

Fig. 27.59 The suction tip should usually be passed just beyond the endotracheal tube tip.

three distinct categories: firstly, the premature neonate who has been ventilator-dependent since birth and repeatedly fails attempts at extubation; secondly, the infant or baby who has breathed spontaneously but then fails extubation after a subsequent surgical procedure; lastly, the infant or older baby who has been readmitted and intubated for LTB or croup, pneumonia, epilepsy control or asthma, subsequently failing extubation. This last category may include children with neurological impairment, such as children with cerebral palsy.

Extubation failure implies that the baby is unable to maintain adequate arterial oxygenation and/or that the P_{aCO_2} has become unsustainably high. Table 27.21 lists possible causes for such failed extubation. Airway obstruction is only one of the important factors and each of the causes should be excluded. In simple terms, successful extubation requires:

1. respiratory drive
2. neuromuscular function
3. adequate cardiac function and pulmonary gaseous exchange
4. clear unobstructed airways
5. no significant sepsis.

In our experience, the most common causes for neonatal intensive care extubation failure are chronic lung disease, apnoea of prematurity, sepsis, airway obstruction or multifactorial causes. Laryngomalacia is probably more common than we think (see below).

Assessing a preterm baby prior to first extubation involves consideration of all these factors. As a broad guideline, a successful outcome is likely if the infant weighs over 1000 g, if there is an air leak around an age-appropriate ETT at less than 20 cmH₂O peak ventilator pressure, if oxygen saturations are being maintained in 35% oxygen or less and if the ventilator requirements have been weaned to satisfactory rates. A rate of 10–15 per minute with peak inspiratory pressure of 12 mmH₂O for a baby under 1 kg, and less than 18 mmH₂O for a baby over 1 kg, is a very rough guide.

Table 27.21 Causes of extubation failure

General sepsis

Management of extubation failure

If extubation fails because of airway obstruction, a retrieval after a period of 2–4 days on systemic dexamethasone, an acid-blocking agent, and heavy sedation or paralysis to reduce tube movement may be successful.

Where there have been repeated failures of extubation, the paediatric ENT surgeon should assess the airway at MLB. The treatment of choice will depend upon the endoscopic findings. If there is relatively little airway trauma but some generalised oedema reducing the laryngeal or subglottic airway, then a further period of therapeutic reintubation may be successful. Sometimes the airway obstruction can be corrected endoscopically, for example by vaporising acquired subglottic cysts or prominent laryngeal granulations with a CO₂ laser. Extubation will then become possible 48–72 hours later. Where there is incipient or early SGS with oedema but a near-normal and clear airway at the level of the vocal cords and above, an anterior cricoid split operation can be undertaken. If the SGS is more severe and the fibrous tissue more mature, then an SS-LTR, employing a costochondral graft to augment the airway, may be chosen if the baby's weight is sufficient. The reconstruction is supported by an ETT for 1–2 weeks, and, if successful, subsequent extubation allows avoidance of a tracheostomy.

Where there is severe transglottic inflammation with granulations or oedema in the supraglottis as well as the subglottis, then a tracheostomy is advised, as the entire larynx cannot settle with the continued presence of an ETT. Figure 27.60 shows laryngeal granulations and exposed cartilage following prolonged complicated intubation. Very early reassessment of the larynx at endoscopy is advisable in such a situation. If after 3 weeks the inflammation has settled and the airway is adequate, tracheostomy decannulation should proceed. Unnecessary prolongation of the duration the tracheostomy is left in situ may otherwise exacerbate the development of progressive SGS.

Fig. 27.61 Vallecular mucus retention cyst obstructing the airway at the tongue base.

Laryngotracheal airway obstruction: conditions and management

Laryngomalacia

Laryngomalacia is the most common cause of infant stridor. It results from laxity of the supraglottic structures: the epiglottis and the mucosa over the cuneiform and arytenoid cartilages can be sucked into the airway on inspiration. The epiglottis is usually curled and omega-shaped and there are both short and tall aryepiglottic folds tethering the arytenoid mucosa to the epiglottis. Laryngomalacia is seen with associated reflux. The airway obstruction and increased intrathoracic negative pressure will increase acid reflux. Typically it presents with inspiratory stridor after the first few weeks (sometimes days) of life. It tends to increase in severity and is often worse on feeding and sleeping supine. The cry will be normal. It is twice as common in boys. The natural history is for self-correction with growth over a 12–24-month period, but it can persist. The diagnosis should usually be confirmed with endoscopy. Treatment is often expectant; however, when there is progressive or continuing stridor with marked recession and respiratory effort, the baby will fail to thrive. If the weight charts show a consistent fall-off down the percentiles, then surgical correction should be undertaken. The endoscopic operation of aryepiglottoplasty (or supraglottoplasty) involves trimming the redundant mucosa and cuneiform cartilages away, and freeing the tethered aryepiglottic folds with microscissors. It is usually highly successful for posterior laryngomalacia, but there is a risk of supraglottic stenosis from scarring. When the laryngomalacia is of an anterior type, involving the epiglottis prolapsing back or into the laryngeal introitus, surgery may not be successful. Some paediatric ENT surgeons advocate an extended supraglottoplasty, resecting the lateral free edges of the curled epiglottis as well. Severe cases of laryngomalacia, not suitable for this endoscopic surgery, may require a tracheostomy, but this is rare.

Airway cysts and webs

Congenital laryngeal (mucus retention) cysts, laryngeal saccule cysts and supraglottic cysts can present in very early life or at a few months with stridor. A mucus cyst of the vallecula at the tongue base can present early with UAO and stridor or stertor. Lateral soft-tissue X-rays may be helpful, but these cysts are definitively diagnosed and treated endoscopically (Fig. 27.61).

Acquired subglottic cysts are commonly found in previously intubated infants, most frequently arising on the left-hand side. They will present with stridor sometimes at the time of a respiratory infection. They can be cured by laser vaporisation at endoscopy (Tierney et al. 1997).

Congenital webbing of the larynx, in which the vocal cords are fused together anteriorly, is rare, and will present with stridor and a posterior laryngeal airway. Open surgery and stenting with a keel are usually required and there is frequently an associated congenital subglottic stenosis requiring a cartilage graft reconstruction as well.

Vocal cord paralysis

Vocal cord paralysis can be unilateral or bilateral, and congenital or acquired. Congenital causes include Arnold–Chiari malformation, other neurological disease and birth trauma, while acquired causes may be from neck trauma or open-heart surgery. Even congenital cases can show spontaneous recovery of movement with development and age. Unilateral cord palsy will present with a weak or husky cry and sometimes feeding difficulty. Stridor is often present only if there is coexistent airway swelling. Swallowing difficulties with aspiration over the long term are sometimes seen. Bilateral cord paralyses, by comparison, will present with inspiratory or biphasic stridor with a vocal quality to the inspiratory noise. The cords lie very close to the midline, restricting the airway. Diagnosis is made at a dynamic microlaryngoscopy. Unilateral cases require no intervention, but bilateral cord paralysis often requires a tracheostomy.

Fig. 27.62 Type 1 congenital posterior laryngeal cleft.

Croup

LTB or croup is usually managed by paediatricians and only involves the ENT surgeons when there have been multiple failures of extubation (see above). Then, endoscopy (MLB) is indicated for diagnosis, and occasionally laser reduction of laryngeal granulations. The ex-premature baby requiring intubation for subsequent croup, however, is at increased risk of developing SGS.

Congenital posterior laryngeal cleft

A congenital laryngeal cleft occurs in the posterior larynx when there is failure of closure of the tracheo-oesophageal groove as high as the interarytenoid level, and a degree of failure of fusion of the posterior cricoid cartilage lamina. There are numerous classifications described (Mounthong and Holinger 1997), but the most commonly accepted one is that of Benjamin and Inglis (1989). A type 1 cleft represents a failure of mucosal fusion in the posterior larynx, with the open notch reaching the level of the vocal cords but not affecting the posterior cricoid plate (Fig. 27.62). A type 2 cleft notches into the cricoid cartilage below the cords. In a type 3 cleft there is complete cleft of the posterior cricoid cartilage and mucosa extending into the cervical trachea. The type 4 cleft extends down into the thoracic trachea (laryngotracheo-oesophageal cleft), even to the carina or beyond.

Type 1 clefts may present late, with repeated aspiration pneumonias and maybe inspiratory stridor similar to that of laryngomalacia. Type 2 and 3 clefts are more likely to present in early life, with airway embarrassment requiring ventilation and with failed extubations. The type 4 cleft may be an immediate neonatal emergency, with great difficulty maintaining an adequate ETT position to ventilate the baby, as the tube tends to prolapse into the oesophagus. Such severe type 4 laryngeal clefts are often incompatible with long-term survival. The diagnosis is always confirmed by MLB.

Management of posterior laryngeal clefts

The type 1 clefts and some type 2 clefts can be repaired surgically from an endoscopic approach. Deeper type 2 clefts and worse will require an open neck or neck and median sternotomy approach. The cleft is repaired in layers, inserting a tibial periosteal graft in

Fig. 27.63 Severe subglottic stenosis.

the trachealis region and perhaps a cartilage graft at the posterior cricoid level. The baby usually needs a tracheostomy as well. Tracheomalacia of the airway remains a significant problem in these challenging conditions and type 4 clefts still carry a very high mortality rate.

Subglottic stenosis

In over 95% of babies, SGS is considered acquired (Cotton et al. 1989), following prolonged intubation of low-birthweight premature infants, many of whom also develop chronic lung disease. The incidence varies but in our institution it occurs in approximately 2.5% of intubated, severely preterm babies. SGS can be congenital, when the unintubated baby is born with stridor. In these cases, endoscopy shows a narrowed, sometimes pear-shaped cricoid region or underriding of the first tracheal cartilage ring. If infants with a congenitally narrow subglottis do require intubation, the use of a standard-sized tube in this situation will cause trauma and may lead to a combined congenital and acquired SGS. The Cotton classification describes the severity of the stenosis, grade I representing up to 50% reduction in lumen cross-section, grade II 50–70%, grade III 70–99%, and grade IV complete stenosis with no lumen. The percentage can be read off a chart according to the size of ETT in relation to age (Myer et al. 1994). Figure 27.63 shows a mature severe SGS.

Factors influencing the development of SGS have been studied (Sherman et al. 1986) and are similar to those for failed extubations. The duration of intubation, the number of ETTs inserted, the duration of mechanical ventilation, the presence of postextubation stridor and the size of the ETT in relation to gestational age are significantly correlated with the development of SGS.

The management of SGS will depend upon its severity and evolution. The mildest cases may be managed conservatively, and, with growth, the condition can improve. Early oedematous SGS may be treated by the cricoid split operation and more severe mature stenoses are likely to require laryngotracheal reconstruction surgery or cricotracheal resection. A tracheostomy is frequently required for a number of years in these difficult cases.

Fig. 27.64 Technique of laryngotracheal reconstruction.

Cricoid split

When there is failure of extubation caused by persistent isolated subglottic oedema, granulations or early soft or incipient SGS, then an open anterior cricoid split operation will often allow subsequent successful extubation. The neck is approached from a horizontal skin crease incision, the cricoid ring and adjacent airway are divided vertically, preserving the vocal cords at the anterior commissure and the baby is then reintubated with a large-sized ETT. This procedure allows oedema fluid to escape from the subglottic region, and the enlarged subglottis will usually heal quickly with an anterior fibrous union. Extubation is attempted, despite an absence of air leak, after 2–7 days following the use of systemic steroids and ranitidine. Tube movement should be kept to a minimum.

If there is accidental extubation, the risk of creating a false passage into the neck on reintubation can be reduced by rotating the ETT through 180° as it is passed through the cords and asking an assistant to apply light digital pressure to the anterior neck wound. The use of a neck drain to avoid surgical emphysema is advised until well after successful extubation.

The reported success rate for cricoid split surgery is between 69% and 75% (Grundfast et al. 1985); however, this procedure is not without potential complications, and failures will require a tracheostomy. In our own experience, the success rate was over 80%, but this was in a highly selected population (Morrison and Wareing 1999). VLBW neonates with a higher oxygen requirement are less likely to have a successful outcome.

Alternative procedures are laryngeal reconstruction, or cricotracheal resection (Fig. 27.64).

Subglottic haemangioma

Subglottic haemangiomas usually present after 6 weeks of age, with progressive stridor and recession. They can be unilateral or bilateral and are seen as a soft smooth red swelling in the subglottis

Fig. 27.65 Unilateral subglottic haemangioma.

(Fig. 27.65). The haemangioma enlarges over the first year or so, and the airway may become compromised, requiring tracheostomy in about 60% of cases (Chatrath et al. 2002). The presence of a cutaneous haemangioma may be a clue to the subglottic diagnosis. The natural history will be of spontaneous resolution over a few years.

MLB under general anaesthesia is required to make the diagnosis. The subglottis shows a smooth dark red swelling on one or both sides, more bulbous in the posterior airway.

Management of subglottic haemangioma

Small haemangiomas can be monitored endoscopically until they regress. If the airway is more significantly compromised, the choice is between a tracheostomy or an attempt to reduce the haemangioma and avoid or reverse a tracheostomy. Episodes on systemic steroids (prednisolone) or intralesional steroids can be beneficial and avoid a tracheostomy, but long-term systemic steroid therapy is not advised because of adverse side-effects. Laser vaporisation of some of the haemangioma may improve the airway and allow avoidance of tracheostomy. Formerly, the CO₂ laser was employed, but results were disappointing. In one large series, the time to resolution of subglottic haemangiomas did not appear to be reduced by CO₂ laser therapy (Chatrath et al. 2002). The physical characteristics of the KTP laser, with deeper penetration into the red spectrum of the haemangioma, may prove a better choice in the future.

A medical therapy for haemangioma has proved successful recently: the administration of propranolol has promoted involution of the haemangioma. In our institution we have employed a regime using 1 mg/kg/day in three divided doses for week 1, increased to 2 mg/kg/day after that for 9–12 months. Careful blood monitoring is important, including glucose, and weight charts may influence dosing. Initially pulse and blood pressure are recorded every 30 minutes then weekly over the whole treatment period. The

resolution has been gradual so for subglottic haemangioma surgery might still be required as prolonged intubation, whilst awaiting involution, has led to airway damage and stenosis.

For those patients who required a tracheostomy, the mean time from diagnosis to decannulation was 30 months (Chatrath et al. 2002). In order to avoid a prolonged period with a tracheostomy, thereby reducing morbidity and enhancing language development, open single-stage excision of the haemangioma by a cricoid split approach and submucosal dissection, with or without a costal graft insertion, has achieved good results, with 80% successful extubation at the first open operation (Froehlich et al. 1995; G Morrison unpublished data 2003).

Vascular compression (rings and slings)

Investigation

The baby or infant with stridor always requires investigation. Particularly where there is evidence of a cardiac condition or associated swallowing difficulty (dysphagia lusoria), a barium swallow X-ray can be helpful. This may demonstrate a congenitally abnormal vascular ring or sling compressing the oesophagus, the trachea or both structures.

Echocardiography can also demonstrate abnormal vessels in the chest, but as ultrasonography expertise is mostly focused on the heart itself, this investigation can miss some mediastinal vessels.

A diagnostic MLB remains the most important investigation and will visualise any pulsatile vascular compression with secondary tracheomalacia or bronchomalacia.

An MRI or CT scan of the thorax will allow clarification of the configuration of the great vessels and detect compression of the trachea or main bronchi by an aberrant vessel such as a double aortic arch (Fig. 27.66) or an aberrant left pulmonary artery. Three-dimensional image reconstructions are very helpful.

Fig. 27.66 Bronchoscopic view of double aortic arch, above the carina.

Management of vascular anomalies

Once the diagnosis has been confirmed with MLB, echocardiography and scanning, the treatment of the condition is surgical correction by paediatric cardiac surgeons. Even after this, soft-tissue swelling will frequently compromise the tracheal or bronchial airway for many months. When necessary, a tracheostomy will treat this by stenting the distal trachea open until natural resolution occurs. If one main bronchus is occluded, then intraluminal bronchial stenting can be undertaken. This is not without complications, however. Palmaz metal expandable mesh stents (Johnson and Johnson Interventional Systems, Warren, NJ) are inserted at bronchoscopy or under radiological screening and are well accepted but become incorporated into the mucosal wall and cannot be easily removed at a future date. Silastic 'hood' stents can be changed and removed, but may lead to more troublesome granulations in the airway. Stenting is advised only when the condition remains life-threatening and other measures have failed.

Congenital microtrachea

This condition, also known as long-segment congenital tracheal stenosis and as stove-pipe trachea, occurs when some or all of the trachea forms with complete tracheal cartilage rings, rather than an open D configuration. There is a large range of severity, but, as the rings are smaller in diameter than normal and do not enlarge at a normal rate, stridor tends to become progressively worse, with increased oxygen needs, over early life. Presentation may be from birth for severe stenoses or only later in childhood for the less severe cases. The microtrachea can be an isolated anomaly, but it is commonly associated with a vascular anomaly, typically an aberrant left pulmonary artery, which passes to the right before looping around the back of the stenotic trachea to reach the left side of the mediastinum (Fig. 27.67).

Management of congenital tracheal stenosis

The mildest cases can be treated conservatively with serial endoscopy. Where there is an associated vascular anomaly, this will require correction surgically. Numerous surgical techniques have been described to correct the microtrachea itself. Short-segment stenoses can be managed by resection and end-to-end anastomosis of the trachea. Longer segments can be treated by a slide tracheoplasty operation, which widens the diameter at the same time as shortening it (Cunningham et al. 1998; Lang et al. 1999). Pericardial patching to a split open trachea has also been employed, but collapse and lack of rigidity are problems with this technique (Backer et al. 2001). All of these surgical treatments are carried out under cardiac bypass. Finally, the most severe stenoses have been treated by transplant of cadaveric tracheas (Herberhold et al. 1999). This involves many months of intraluminal stenting with treatment of troublesome granulations.

Tracheomalacia, bronchomalacia

Tracheomalacia or bronchomalacia can be primary or secondary. When primary, there is generalised lack of support of the airway, with weak collapsing cartilage, causing a flattening of the normal D-shape cartilages on respiration and excessive collapse of the trachealis soft tissue into the lumen on respiration. This may involve one or both of the trachea and bronchi. The generalised tracheomalacia is likely to be self-correcting with growth. Secondary malacia occurs where there is extrinsic compression of the airway from an abnormal vessel, an unusually overriding aorta, or from a

Fig. 27.67 Congenital long-segment tracheal stenosis with aberrant left pulmonary artery.

mediastinal tumour. It can also occur as localised tracheomalacia following cartilage resorption at the site of a tracheostomy or other airway surgery. Tracheomalacia will present with biphasic or primarily expiratory stridor, recession and a gruff barking cough. It is made worse by increased activity or respiratory effort, or concurrent infection.

Investigations for tracheobronchomalacia

Diagnostic MLB will confirm the tracheomalacia or bronchomalacia, so long as the study is dynamic, with the baby breathing spontaneously under a light general anaesthetic without CPAP from the anaesthetic circuit. Flexible bronchoscopy on a neonatal intensive care unit, through an ETT, will also allow this assessment if there is no positive airway pressure. Such an assessment, however, can exaggerate the degree of malacia and in a flexible assessment of any normal infant making significant respiratory effort there will be some airway collapse and bulging in of the trachealis with respiration, because of the negative intrathoracic pressure. Radiology using a contrast bronchogram under screening or video recording will also demonstrate a malacic airway and help to localise the area of obstruction or image the tree distal to an endoscopically unpassable stenosis.

Management of tracheobronchomalacia

Primary malacia can be treated by positive-pressure ventilation or CPAP until there is sufficient improvement. This conservative approach may not always be possible, however, in which case

tracheostomy or intraluminal stenting is considered. Localised tracheomalacia, if severe, may require a tracheostomy, the tube stenting the airway open. Sometimes, customised longer tubes are required. Secondary tracheomalacia will tend to self-correct once the causative external compression is rectified, but airway stenting or tracheostomy can still be required for a period. [Furman et al. \(1999\)](#) reviewed six cases employing a Palmaz expandable stent, reporting two deaths and three long-term successes. Granulation formation within the airway was encountered. Aortic compression of the trachea can sometimes be improved by aortopexy surgery, in which the aorta is hitched anteriorly towards the sternum. The approach can be through an anterolateral thoracotomy, a stenotomy or at transthoracic endoscopy.

Cartilage malacia following localised surgery such as tracheostomy can require tracheal reconstruction with costal cartilage grafting or excision and end-to-end anastomosis.

Bronchoscopy for atelectasis and air trapping

Infantile pneumonias are usually treated medically, with mechanical ventilation, endotracheal suctioning and physiotherapy where necessary. Bronchoscopy is not generally considered as a first-line adjunctive treatment. However, on occasions, rigid bronchoscopy under light general anaesthesia will lead to an improvement in the condition. Firstly, if the segmental or main bronchi are obstinately plugged with mucus casts, it may be possible to clear these at bronchoscopy by bronchial saline lavage and aspiration. The topical irrigation at bronchoscopy of a mucolytic agent such as rhDNase therapy ([Durward et al. 2000](#)) has been highly effective in this regard in a small number of cases. Bronchoscopy can also allow accurate collection of a tenacious mucopurulent specimen for microbiology.

Finally, unilateral air trapping and emphysema with secondary mediastinal shift in neonates can be compromising; if the problem persists, a rigid bronchoscopy to clear the segmental bronchi and inflate the collapsed regions can restore a more symmetrical ventilation.

Tracheostomy

In the 19th century, indications for tracheostomy included inhaled foreign bodies, diphtheria and croup, but the mortality was very high. In recent years, indications have changed. Infective indications, especially bacterial, are much reduced, although intubation trauma to the laryngotracheal airway following ventilation for croup (LTB) remains a common problem. Increasing survival of VLBW babies and babies with multiple congenital abnormalities has led to a lowering of the average age of patients undergoing paediatric tracheostomy, more than half of which procedures are carried out in babies under 1 year old ([Ward et al. 1995](#)). There is often continued need for long-term tracheostomy in these infants. Also, more paediatric tracheostomies are carried out for surviving babies with congenital UAOs as well as for those with neuromuscular diseases.

Broadly, there are three categories of indication for a tracheostomy: (1) for airway obstruction; (2) for assisted prolonged ventilation (especially if there is evidence of airway trauma); and (3) to provide pulmonary toilet and/or non-ventilatory support. This last category will include infants with neurological impairment or immaturity who are ventilator-dependent using an ETT but can be weaned to spontaneous respiration with a tracheostomy and supportive airway toilet. This process allows rehabilitation away from an intensive care setting. When long-term ventilation is required, the continued use of endotracheal intubation rather than

Table 27.22 Airway indications for tracheostomy

Airway obstructed above larynx (e.g. lymphangioma, Pierre Robin)
Tongue base collapse, glossoptosis
Severe laryngomalacia
Laryngeal granulations and airway trauma (postintubation)
Subglottic stenosis
Subglottic haemangioma
Respiratory papillomatosis
Bilateral vocal cord palsy
Bilateral cricoarytenoid joint fixation
Vascular compression – aberrant pulmonary artery, double aortic arch
Primary tracheomalacia
Microtrachea and congenital bronchopulmonary deformity

tracheostomy is appropriate so long as the intubation is not causing airway trauma or stenosis.

In our institution, in a series of 65 cases over 3 years, almost half the paediatric tracheostomies performed were for airway obstruction; only 8.7% were for an acute airway infection and 12.3% were required for a congenital airway anomaly. The remainder of patients in this series required a tracheostomy for long-term ventilation, airway toilet or non-ventilatory respiratory support. Table 27.22 summarises the common causes of airway obstruction requiring tracheostomy.

Posttracheostomy ward care

Postoperatively, a chest X-ray is routine to confirm the tracheostomy tube position and that there are no complications such as consolidation or pneumothorax. The tracheostomy tapes and the tube should not be changed or removed for the first week, except in airway distress, in order to allow a good tract to develop. A member of the medical staff should perform the first tube change; thereafter, weekly changes, or more frequently if there is a need, are advised. Velcro tracheostomy tapes can be used after the first tube change. The tube must be kept patent at all times. Constant humidification of the ventilated or inspired air is recommended, to stop drying of obstructive secretions. If the baby is self-ventilating, formal humidification or the application of a 'Swedish nose' (Portex Thermovent T attachment) will achieve this.

Regular tracheostomy suctioning will be required to keep the airway free of mucus secretions. A flexible catheter is inserted just to the level of the tracheostomy tube tip, and then the suction is activated by occluding its vent with a thumb while the suction tube is gently swivelled between finger and thumb as it is withdrawn. Only occasionally is it necessary to run the suction tube significantly beyond the distal tube tip, to or beyond the carina. Overzealous suctioning of this type can lead to tracheal trauma with bleeding, and granulation formation.

When a tracheostomy is inserted for long-term airway ventilation in a neonate with chronic lung disease (bronchopulmonary dysplasia), initial ventilation may be unexpectedly difficult owing to there being a much larger air leak around the tracheostomy tube up through the larynx than was possible when the long, snugger ETT was employed. Higher ventilator pressures may therefore be needed, and relatively larger tracheostomy tubes are often required, which may damage the trachea. This is one reason why tracheostomy is not necessarily a helpful procedure for the baby with severe lung disease who still requires long-term ventilatory support.

Complications and mortality of tracheostomy

Accidental decannulation and tube obstruction remain the most life-threatening complications. If the attempt to reinsert the tube results in a false passage, the attempts at ventilation will fail and can lead to pneumomediastinum and pneumothorax. Other complications include bleeding, surgical emphysema, wound infection, chest infection, airway trauma from overly vigorous suctioning and cardiorespiratory arrest.

Late sequelae of tracheostomy include the frequent formation of a suprastomal granuloma within the trachea, tracheomalacia, deglutition difficulties, language delay, chest infections and subsequent persistence of a tracheocutaneous fistula after decannulation. The most serious late complications remain tube obstruction and accidental displacement. Massive haemorrhage is rare, as is tracheal stenosis.

Mortality from tracheostomy is difficult to define. The range for paediatric published series is an overall raw mortality of 11–40% (Dutton et al. 1995). In our most recent series, the overall mortality is 19%. Tracheostomy tube-related deaths, however, are rare, ranging from 0.5% to 3.4% in different reported series (Dutton et al. 1995). Ward et al. (1995) reported a tracheostomy-related mortality rate of 2.9%, with mucus plugging of the tracheostomy being the most common cause of death.

There is a strong association between prematurity and mortality in infants with a tracheostomy, and higher comorbidity scores correlate with higher mortality rates. In one series (Gianoli et al. 1990), 80% of deaths were in preterm infants, and among those who were under 3000 g weight at the time of tracheostomy the mortality rate was 64%. The tube-related mortality rate, however, was low, at 1.6%. In our institution, the raw mortality rate among infants requiring a tracheostomy at under 1 year of (uncorrected) age was 25.6% and that among severe preterm infants requiring long-term ventilation was very much higher. Tracheostomy is not a cure-all treatment for these high-risk infants, and must be undertaken only after careful evaluation.

Home tracheostomy care

Home tracheostomy care will need to be arranged and will include local support services as well as guardians learning to care for the tracheostomy, change the tubes, and acquire appropriate resuscitation expertise. Special precautions are required for the baby with a tracheostomy, and include care with baths, refraining from swimming, and avoiding foreign bodies such as sand, dirt, talc or aerosols from entering the stoma. Care is also required with clothes and bibs and sleeping positions, to ensure that these items or the chin does not occlude the tracheostomy tube. A tube extension and 'Swedish nose' help avoid chin dipping as a cause of occlusion.

Decannulation from tracheostomy

The earliest possible decannulation is desirable. Prolonged placement of a tracheostomy tube, even in developmentally normal children, results in language delay (Jiang and Morrison 2003). The tracheostomy can be removed after definitive correction or spontaneous resolution of the underlying condition for which the tracheostomy was required and after the airway has been assessed at dynamic endoscopy. Prior to successful tracheostomy decannulation, there should be no serious aspiration or recurrent chest infections, no need for regular tracheal toilet and no need for assisted ventilation. The upper airway must be adequate and assessed at MLB, which should include removal of any obstructing suprastomal granuloma, and assessment of vocal cord mobility and airway collapse on respiration.

Once the infant is considered fit for decannulation, the usual practice would be to try a ward decannulation procedure. The tracheostomy tube is downsized to the smallest available (usually a size 3 Shiley) and the tube is then occluded with a bung or tape for short periods, by day, with observation and saturation monitoring. The tube is then occluded for progressively longer periods if tolerated; when 24 hours of occlusion is achieved, the tube can be removed and an occlusive dressing applied to the fistula site. If this ward decannulation protocol fails, the airway will require reassessment. Sometimes a surgical decannulation is required. In this case, the tracheostomy is formally reversed and closed at surgery, usually with removal of an obstructive granuloma or repair of a suprastomal tracheal collapse. The baby is then managed on an intensive care unit, intubated and ventilated with relatively little tube movement for 2–7 days prior to elective extubation (Al-Saati et al. 1993).

Antenatal airway obstruction and EXIT

Increasing sophistication of antenatal diagnosis, initially with ultrasound, increasingly allows the detection of potential airway problems that will become apparent at birth or even beforehand. Fetal MRI is helpful to define the pathology further. When a prenatal diagnosis of airway obstruction is made, a multidisciplinary approach to the pregnancy and birth is important. If long-term

survival seems possible, it is feasible to plan a special delivery by the EXIT procedure (Ward et al. 2000). This procedure involves delivering the head and upper torso of the baby through a caesarean section approach while maintaining the uteroplacental blood flow and maternofetal gas exchange. This allows time for the airway obstruction to be corrected and an airway secured, prior to full delivery and ligation of the umbilical cord.

Mass lesions obstructing the fetal airway will be detected on ultrasound. Cystic hygromas are common, but only those hygromas which seem to involve the pharynx or cause airway compression are likely to cause neonatal airway obstruction. Once an obstructing lesion is detected on ultrasound, rapid-sequence fetal MRI is recommended, where transverse, sagittal and coronal planes can be studied.

In a complete laryngeal atresia it may be difficult to see the larynx fully on fetal ultrasound, but the secondary changes in the trachea and lungs are apparent. Because there is total obstruction, the liquor produced in the lungs builds up, causing gross tracheal dilatation and hypoechogenic lungs. There is often polyhydramnios, an inverted diaphragm and ascites. This is described as congenital high airway obstruction syndrome and it represents complete airway obstruction (DeCou et al. 1998). If the fetus can be brought to maturity, the EXIT procedure with tracheostomy is the management of choice.

Introduction

Neonatal cardiovascular disease can be primary or secondary, congenital or acquired, structural or functional. Whatever categories of abnormality are concerned, a similar systematic approach to history, examination and investigation is required to allow correct management. In many situations, an understanding of fetal as well as of neonatal cardiovascular physiology is necessary. In this chapter the approach is pathophysiological, with particular conditions being considered in the most appropriate category.

Fetal circulation

Much of the information about the fetal circulation has been derived from animal studies. Increasingly sophisticated, non-invasive, ultrasound assessment of the human fetal circulation has demonstrated important differences in the human fetus.

Fetal circulatory pathways

The fetal circulation consists of parallel systemic and pulmonary pathways in contrast to the normal postnatal circulation, in which the systemic and pulmonary circulations exist in series (Fig. 28.1). For the most part, prenatal survival is possible with even major structural cardiovascular malformations, provided that either the right or left ventricle is able to pump blood derived from the great veins into the fetal aorta. It is this remarkably adaptive nature of the fetal circulation which enables fetuses with complex malformations such as those with atresia of either of the semilunar valves to survive throughout pregnancy. In the fetus, oxygenated blood returns from the placenta via the umbilical vein into the inferior caval vein, either through the portal system or through the venous duct. The proportion of blood channelled through these different routes changes as pregnancy progresses and will adapt continuously to the metabolic demands of the fetus by flow regulation in the venous duct. The stream of inferior caval blood entering the right atrium is divided as it hits the superior rim of the oval foramen and the majority of the blood enters the left atrium through the foramen. As pregnancy advances, the proportion crossing into the left atrium falls. Superior caval vein blood enters the right atrium and the majority will enter into the right ventricle via the tricuspid valve. Almost all of the right ventricular (RV) output will be directed through the arterial duct into the systemic circulation, bypassing the high-resistance pulmonary circulation. The proportion of pulmonary blood flow also changes with gestation, increasing during the third trimester. Just as in postnatal life, the fetal pulmonary vascular bed is reactive. Fetal pulmonary blood flow can be increased by manipulation of the pulmonary vasculature bed with pulmonary vasodilator agents (such as oxygen) administered to the mother (Rasanen et al. 1998). As pregnancy progresses, the effective cardiac output increases to a maximum of approximately 250 ml/kg/min by term, with the right ventricle contributing 55% and the left

Fig. 28.1 Schematic representation of the fetal circulatory pathways. The placenta is drawn to a greatly reduced scale. (Reproduced with permission from Gray's Anatomy, 40th ed. Elsevier Inc. Fig 59.17.)

ventricle 45% of the fetal cardiac output. Of the combined output, 65% returns to the placenta and 35% to the fetal organs and tissues (Rudolph 1974).

Function of the fetal heart

Compared with the normal adult heart, there are a number of differences both within the fetal heart itself as well as between the physiological environment during fetal and postnatal life which explain many of the observations of fetal cardiac function. In early fetal life, the expression of contractile proteins is different from the postnatal pattern (Hunkeler et al. 1991). In addition, the expression of different types of collagen within fetal heart muscle results in reduced compliance of the fetal heart compared with the postnatal heart (Marijjanowski et al. 1994). With advancing gestation, there is continuing maturation of excitation–contraction coupling as well as increasing autonomic innervation (Grant 1999). As a result, the immature fetal heart is much less compliant and less able to generate contractile force than its adult counterpart, for the same degree of stretch. However, the observation that the Starling curve in the fetus is blunted should not be attributed to the differences in the fetal myocardium alone. It is significantly influenced by the external constraints existing around the heart in the fetus, including the fluid-filled lungs and rigid chest wall.

Changes at birth

The most dramatic events that occur with birth are a shift from a circulation in parallel to one in series, as well as a marked increase in cardiac output from both ventricles. At term, the cardiac output from each ventricle approximately equals the combined cardiac output from both ventricles in the immediately preterm fetus. With inspiration, there is a rapid fall in pulmonary vascular resistance (PVR), as lung expansion allows new vessels to open and existing vessels to enlarge. Reduced resistance and decreased pulmonary artery pressures increase pulmonary blood flow. Simultaneously, the lower resistance placental circulation is removed from the systemic circulation as the cord is cut. The increased preload occurring from placental return can now be converted into useful increased cardiac output, once the external constraints of fluid-filled lungs around the heart are replaced by more compliant air-filled lungs. The sudden increase in oxygen tension produced by breathing alters local prostaglandin synthesis, resulting in a constriction of both the arterial and venous ducts. For most neonates, functional closure of the arterial duct will have occurred within 24–72 hours and anatomical closure is complete within 1–2 weeks. The oval foramen and venous duct may remain patent for some time after birth, with the potential to allow shunting. This can mask the signs of underlying structural congenital cardiovascular malformations, such as infracardiac total anomalous pulmonary venous drainage or, occasionally, transposition of the great arteries (TGA). The oval foramen is functionally closed in the majority of cases by the third month of life. Continued patency may contribute to clinical problems in some conditions (Table 28.1).

Fetal cardiology

Diagnosis

Fetal cardiac anatomy, function and rhythm have been determined by transabdominal scanning from 18 weeks' gestation for the last two decades (Allan et al. 1985). An approach using both abdominal and (when necessary) transvaginal scanning in high-risk cases at 10–13 weeks allowed interpretable images in over 80% of cases

Table 28.1 Clinical problems associated with failure of closure of the foramen ovale, ductus venosus and ductus arteriosus after birth

Foramen ovale	Allows right-to-left shunting in persistent pulmonary hypertension of the newborn and other cardiac/respiratory conditions with increased right heart pressures
Ductus venosus	No definite problem identified (except in obstructed total anomalous pulmonary venous connection: see text)
Ductus arteriosus	Associated with major respiratory and other problems in preterm infants Important left-to-right shunting only rarely seen in the newborn period in term infants with patent ductus arteriosus

Table 28.2 Indications for detailed fetal echocardiography

Autosomal dominant condition with cardiac implications in either parent
Structural heart disease in parent or previous sibling
Structural heart disease in two or more family members
Maternal disease with increased risk of fetal cardiac problem, e.g. diabetes mellitus, collagen vascular disease
Maternal teratogen exposure, e.g.: <ul style="list-style-type: none"> infection: rubella medication: anticonvulsants, lithium, warfarin alcohol
Abnormal nuchal translucency in the first trimester with normal karyotype or karyotype declined
Abnormal four-chamber view or suspected congenital heart disease on routine midtrimester scan
Extracardiac abnormalities in the fetus
Suspected syndrome in the fetus
Maternal prostaglandin synthetase inhibitor therapy
Abnormal heart rate/rhythm in the fetus
Hydropic fetus <ul style="list-style-type: none"> Consider in in vitro fertilisation pregnancies

(Huggon et al. 2002), with a probable low false-positive rate, although verification was incomplete. Screening fetal cardiac anatomy with a four-chamber view at 18 weeks is a routine part of the general anomaly scan, but this will pick up under 50% of cases of structural heart lesions, even in experienced hands (Stümpflen et al. 1996; Bull 1999). Heart lesions picked up by a four-chamber screening scan are generally the more complex ones with a poorer outlook both prenatally and after delivery. If views of the outflow tracts are obtained in addition to the four-chamber view, the range of abnormalities detectable is increased (Carvalho et al. 2002). In particular, transposition, tetralogy of Fallot and similar lesions should be detected.

Detailed evaluation of fetal cardiac anatomy by ultrasound is much more time-consuming and is usually reserved for women with an increased risk of having a fetus with a cardiac problem (Table 28.2). However, when detailed echocardiography was used on all pregnancies, Stümpflen and colleagues (1996) reported 86% sensitivity and 100% specificity. The conditions missed were mainly atrial septal defects (ASDs) and small ventricular septal defects (VSDs). Other workers have pointed out the difficulty in diagnosing

coarctation and total anomalous pulmonary venous connection (TAPVC) in the fetus (Allan 1995). Abnormalities of fetal heart rhythm can be determined by M-mode and Doppler studies.

There are ethical aspects to fetal diagnosis and practitioners in this field need to be sensitive to parental views. Fetal cardiac scanning should be carried out in the context of expertise in all aspects of fetal medicine, including the provision of support to families. The association with non-cardiac abnormalities is strong and these are often major influences in the natural history in utero and after birth, as well as in decisions about continuation of pregnancy. For example, in one study in which cardiac scans were performed for a variety of indications, 70% of fetuses with a cardiac anomaly had an underlying chromosome abnormality (Huggon et al. 2002).

Treatment

Accurate diagnosis of structural heart disease in a fetus allows information to be given to families and provides for greater choice. Some parents will opt for termination of pregnancy and about 5% of fetuses with structural cardiac abnormalities will die in utero (Yates 2004). Cardiac diagnosis and prognosis must be considered in the context of full fetal assessment, as non-cardiac abnormalities may well be more important in determining the overall prognosis. The combination of a structural cardiac abnormality and an extracardiac abnormality will often influence outcome more adversely than anticipated for either lesion alone.

In pregnancies progressing to viability, a cardiac diagnosis will, in a minority of cases, influence place, time or mode of delivery, but non-cardiac factors also need to be taken into account. The most important point with respect to early postnatal management of heart disease is whether or not the lesion is likely to be duct-dependent, thereby allowing prostaglandin to be used before symptoms develop. Progressive underdevelopment of the ventricle in the fetus with severe arterial valve stenosis is well recognised (Simpson and Sharland 1997; Tulzer et al. 2002) and prenatal arterial valve balloon valvuloplasty has been performed with limited proven efficacy (Kohl et al. 2000; Tulzer et al. 2002). Some structural lesions do not progress with advancing gestation and, in those that do, only a tiny minority are suitable for any form of prenatal intervention. There is evidence that fetal diagnosis of severe duct-dependent congenital heart disease (CHD) results in babies reaching a cardiac centre in better condition than those not diagnosed until after delivery (Yates 2004). Benefit from fetal diagnosis in terms of improved survival and morbidity has been shown for coarctation (Franklin et al. 2002), and in improved mortality in transposition (Bonnet et al. 1999) and hypoplastic left heart (Tworetzky et al. 2001), although, in the last two conditions, the benefit from prenatal diagnosis has been difficult to demonstrate (Yates 2004). Reassurance of normality or the chance to prepare for the arrival of an abnormal baby is valued by many parents but has not been formally quantified.

Accurate diagnosis of fetal dysrhythmias is essential to avoid unnecessary intervention and to allow appropriate treatment which can almost always improve the outlook for the fetus with a haemodynamically compromising rhythm disturbance. Diagnosis and management of abnormal fetal rhythms are discussed in the section on neonatal rhythm disturbances (p. 661).

Incidence and aetiology of fetal and neonatal heart disease

Structural CHD occurs in approximately 8 per 1000 live births (Anderson et al. 2002). In populations uninfluenced by fetal

Table 28.3 Distribution of congenital cardiac lesions in newborn infants, median and interquartile (%), obtained from 34 studies involving 26 904 infants

LESION/GROUP	MEDIAN	25 TH –75 TH
Ventricular septal defect	32.0	27–42
Patent arterial duct	6.8	5–11
Atrial septal defect	7.5	6–11
Atrioventricular septal defect	3.8	3–5
Pulmonary stenosis	7.0	5–9
Aortic stenosis	3.9	3–6
Coarctation of aorta	4.8	4–6
Transposition of great arteries	4.4	4–5
Tetralogy of Fallot	5.2	4–8
Common arterial trunk	1.4	1–2
Hypoplastic left heart	2.8	2–3
Hypoplastic right heart	2.2	2–3
Double-inlet ventricle	1.5	1–2
Double-outlet right ventricle	1.8	1–3
Total anomalous pulmonary venous drainage	1.0	1–2
Others	10.0	8–15

(Adapted with permission from Hoffman (2002).)

diagnosis, between 30% and 40% of these children will be symptomatic in early infancy and about two-thirds of them will have been diagnosed by the end of the first year of life. There are various studies on the prevalence of CHD: diagnostic methods and criteria vary, but Table 28.3 gives figures for those presenting in the neonatal period. The true prevalence may be higher than this, because some lesions such as a bicuspid aortic valve are usually excluded. Bicuspid aortic valve occurs in 10–20 per 1000 live births and may be associated with significant morbidity in later life (Ward 2000). An increased prevalence of CHD is also supported by fetal echocardiography data, which have shown that some severe cardiac lesions will result in death in utero (Yates 2004). Furthermore, the effect of prenatal diagnosis on postnatal prevalence and spectrum of disease may be considerable (Bull 1999).

Acquired heart disease, such as endocarditis and myocarditis, may present in the newborn period. Metabolic disorders, which may involve heart muscle, can produce symptoms in the newborn period. There are no reliable data for the incidence of these problems or for the incidence of fetal and neonatal arrhythmias.

Although there have been major advances in the diagnosis and treatment of CHD, understanding of its causes remains limited. Advances in cytogenetics have provided a greater understanding of the role of inherited and environmental factors and their interaction on the development of CHD. Environmental factors such as maternal diabetes, alcohol/drug ingestion and, less commonly, some congenital infections are known to affect cardiac development adversely. The major chromosomal abnormalities such as trisomies 21, 18 and 13 cause syndromes, part of which can include structural

cardiac malformations, and these have been well documented (Table 28.4). Before the advent of fluorescence in situ hybridisation (FISH), standard chromosome analysis revealed chromosomal abnormalities in about 10% of newborns with CHD (Ferencz et al. 1989). Improved genetic techniques, including FISH, cytogenetic techniques and DNA mutation analysis, have confirmed that this prevalence is much higher. An explanation of the genetic techniques and their uses is beyond the scope of this chapter but readers are referred to the American Heart Association statement on the genetic basis for congenital heart defects (Pierpont et al. 2007). Therefore, chromosomal and genetic analysis in neonates with various types of CHD is an important part of their evaluation, particularly because, in some syndromes, the extracardiac manifestations are often less evident and the cardiac abnormalities provide the clue to the diagnosis in the newborn period.

Syndromes associated with CHD, such as 22q11 deletion, Noonan's, Williams, Alagille's, Holt–Oram and others, have been shown to be associated with subtle chromosomal or genetic abnormalities such as deletions or point mutations (Tables 28.4 and 28.5). In some defects there are no associated syndromes but specific genes have been identified in association with particular defects (Tables 28.4 and 28.5). For individuals with CHD or their families, the identification of a genetic cause for the CHD is beneficial. It helps the clinician to explain the mechanism to the family and broadens the context of the diagnosis to other family members.

Such advances have altered the traditional view of a multifactorial basis for the aetiology of CHD shifting towards a genetic aetiology

for an increasing number of lesions. Associated with this is the potential to provide more accurate data about recurrence risk in siblings and offspring of affected parents: this has been shown to be higher when the affected parent is female (Burn et al. 1998).

Clinical implications of adaptation to birth

Normal adaptation

Normal adaptation of the fetal circulation at birth may have adverse haemodynamic effects in some congenital cardiac malformations just as failure of normal changes to occur may be disadvantageous under certain circumstances.

Foramen ovale

If exit of blood from the left atrium through the mitral valve is impaired, the presence of a foramen ovale is important in allowing decompression of the left atrium as it is forced open by abnormally high pressure in the left atrium. Failure of this mechanism by virtue of a small foramen ovale results in pulmonary venous hypertension and respiratory distress. This problem is an important part of the pathophysiology of mitral atresia or hypoplasia. A restrictive foramen ovale is also important in obstructive lesions in the right heart, such as tricuspid atresia, pulmonary atresia with intact ventricular septum and critical pulmonary stenosis. In such

Table 28.4 Representative chromosomal disorders associated with congenital heart disease (CHD)

CHROMOSOMAL DISORDER	MAIN FEATURES	PERCENTAGE WITH CHD	HEART ANOMALY
Deletion 4p (Wolf–Hirschhorn syndrome)	Pronounced microcephaly, widely spaced eyes, broad nasal bridge (Greek helmet appearance), downturned mouth, micrognathia, preauricular skin tags, elongated trunk and fingers, severe mental retardation and seizures; one-third die in infancy	50–65	ASD, VSD, PDA, LSVc, aortic atresia, dextrocardia, TOF, tricuspid atresia
Deletion 5p (cri du chat)	Cat-like cry, prenatal and postnatal growth retardation, round face, widely spaced eyes, epicanthal fold, simian crease, severe mental retardation, long survival	30–60	VSD, ASD, PDA
Deletion 7q11.23 (Williams–Beuren syndrome)	Infantile hypercalcaemia, skeletal and renal anomalies, cognitive deficits, 'social' personality, elfin facies	53–85	Supravalvar AS and PS, PPS
Trisomy 8 mosaicism	Skeletal/vertebral anomalies, widely spaced eyes, broad nasal bridge, small jaw, high arched palate, cryptorchidism, renal anomalies (50%), long survival	25	VSD, PDA, CoA, PS, TAPVR, truncus arteriosus
Deletion 8p syndrome	Microcephaly, growth retardation, mental retardation, deep-set eyes, malformed eyes, small chin, genital anomalies in males, long survival	50–75	AVSD, PS, VSD, TOF
Trisomy 9	Severe prenatal and postnatal growth retardation, marked microcephaly, deep-set eyes, low-set ears, severe mental retardation; two-thirds die in infancy	65–80	PDA, LSVc, VSD, TOF/PA, DORV

Table 28.4 Continued

CHROMOSOMAL DISORDER	MAIN FEATURES	PERCENTAGE WITH CHD	HEART ANOMALY
Deletion 10p	Frontal bossing, short down-slanting palpebral fissures, small low-set ears, micrognathia, cleft palate, short neck, urinary/genital, upper limb anomalies	50	BAV, ASD, VSD, PDA, PS, CoA, truncus arteriosus
Deletion 11q (Jacobsen syndrome)	Growth retardation, developmental delay, mental retardation, thrombocytopenia, platelet dysfunction, widely spaced eyes, strabismus, broad nasal bridge, thin upper lip, prominent forehead	56	HLHS, valvar AS, VSD, CoA, Shone's complex
Trisomy 13 (Patau syndrome)	Polydactyly, cleft lip and palate, scalp defects, hypotelorism, micro-ophthalmia or anophthalmia, colobomata of irides, holoprosencephaly, microcephaly, deafness, profound mental retardation, rib abnormalities, omphalocele, renal abnormalities, hypospadias, cryptorchidism, uterine abnormalities; 80% die in first year	80	ASD, VSD, PDA, HLHS, laterality defects, atrial isomerism
Trisomy 18 (Edwards syndrome)	IUGR, polyhydramnios, micrognathia, short sternum, hypertonia, rocker-bottom feet, overlapping fingers and toes, TEF, CDH, omphalocele, renal anomalies, biliary atresia, profound mental retardation; 90% die in first year	90–100	ASD, VSD, PDA, TOF, DORV, D-TGA, CoA, BAV, BPV, polyvalvular nodular dysplasia
Deletion 20p12 (Alagille syndrome)	Bile duct paucity, cholestasis, skeletal or ocular anomalies, broad forehead, widely spaced eyes, underdeveloped mandible	85–94	Peripheral PA, hypoplasia, TOF, PS (left-sided heart lesions and septal defects less common)
Trisomy 21 (Down syndrome)	Hypotonia, hyperextensibility, epicanthal fold, simian crease, clinodactyly of fifth finger, brachydactyly, variable mental retardation, premature ageing	40–50	AVSD, VSD, ASD (TOF, D-TGA less common)
Deletion 22q11 (DiGeorge, velocardiofacial and conotruncal anomaly face syndrome)	Hypertelorism, micrognathia, low-set posteriorly rotated ears, 'fish mouth', thymic and parathyroid hypoplasia, hypocalcaemia, feeding/speech/learning/behavioural disorders, immunodeficiency, palate/skeletal/renal anomalies	75	IAA-B, truncus arteriosus, isolated aortic arch anomalies, TOF, conoventricular VSD
Monosomy X (Turner syndrome, 45,X)	Lymphoedema of hands and feet, widely spaced hypoplastic nipples, webbed neck, primary amenorrhoea, short stature, normal intelligence	25–35	CoA, BAV, valvar AS, HLHS, aortic dissection
Klinefelter syndrome (47,XXY)	Usually normal-appearing, tall stature, small testes, delayed puberty, emotional and behavioural problems common, variable mental retardation	50	MVP, venous thromboembolic disease, PDA, ASD

ASD, atrial septal defect; VSD, ventricular septal defect; PDA, patent ductus arteriosus; LSV, left superior vena cava; TOF, tetralogy of Fallot; AS, aortic stenosis; PS, pulmonary stenosis; PPS, peripheral pulmonary stenosis; CoA, coarctation of the aorta; TAPVR, total anomalous pulmonary venous return; AVSD, atrioventricular septal defect; TOF/PA, tetralogy of Fallot with pulmonary atresia; DORV, double-outlet right ventricle; BAV, bicuspid aortic valve; HLHS, hypoplastic left-heart syndrome; IUGR, intrauterine growth retardation; TEF, tracheo-oesophageal fistula; CDH, congenital diaphragmatic hernia; D-TGA, D-transposition of the great arteries; BPV, bicuspid pulmonary valve; PA, pulmonary artery; IAA-B, interrupted aortic arch type B; MVP, mitral valve prolapse. (Reproduced from Pierpont et al. (2007), with permission.)

Table 28.5 Single-gene mutations associated with genetic syndromes and congenital heart defects (see Table 28.4)

CONDITION	DEFECT	CHROMOSOME LOCATION	GENE
Syndrome

PS, pulmonary stenosis; ASD, atrial septal defect; HCM, hypertrophic cardiomyopathy; MVP, mitral valve prolapse; Ao, aortic; PA, pulmonary artery; VSD, ventricular septal defect; AVSD, atrioventricular septal defect; TOF/PA, tetralogy of Fallot with pulmonary atresia; IAA, interrupted aortic arch; HOCM, hypertrophic obstructive cardiomyopathy; TGA, transposition of the great arches; AS, aortic stenosis. (Adapted from Pierpont et al. (2007).)			

circumstances, right atrial enlargement and hydops fetalis may occur in utero, but, even if this does not occur, there may be post-natal problems from systemic venous engorgement and poor cardiac output. In the context of TGA, a small foramen ovale results in poor mixing of oxygenated and deoxygenated blood. In many of these conditions, particularly TGA, enlargement of a small foramen ovale by balloon atrial septostomy is an important part of the initial management. In some circumstances, surgical septostomy or septectomy may be indicated, as in mitral atresia. Failure of the foramen ovale to close has the same consequences as the presence of an ASD; indeed, distinguishing between patent foramen ovale (PFO) and ASD in newborn infants can be difficult. The consequences are right-to-left shunting in the presence of structural or functional obstruction to right heart flow and left-to-right shunting otherwise. The balance between favourable and deleterious effects is different for different lesions. In general, left-to-right shunting at atrial level in early infancy is rarely a major disadvantage, whereas right-to-left shunting will worsen systemic arterial desaturation – but this may be less of a disadvantage than very high venous pressures or poor left ventricular filling resulting from poor forward flow through the right heart.

Ductus venosus

Closure of the ductus venosus is of importance in that it removes the possibility of central venous access being obtained via the umbilical vein for monitoring, balloon septostomy or cardiac catheterisation. It will also result in marked deterioration in cases of TAPVC to the portal vein as it will cause severe pulmonary venous obstruction with pulmonary congestion (Fig. 28.2). In this condition, closure of the ductus venosus may not occur until some days after birth. Delay in or failure of closure of the ductus venosus is probably rare and never of significance.

Ductus arteriosus

Closure of the DA will cause marked deterioration in duct-dependent pulmonary and duct-dependent systemic circulations, in the first instance causing worsening cyanosis, and, in the latter, shock and heart failure. Systemic arterial oxygenation in TGA will also deteriorate when the DA closes. These conditions are all discussed in more detail below (see sections on [cyanosis](#) and [collapse](#)).

Fig. 28.2 (A) Anteroposterior chest X-ray in a neonate with obstructed total anomalous pulmonary venous connection showing pulmonary venous congestion and normal heart size. (B) Volume-rendered three-dimensional magnetic resonance imaging reconstruction in the same patient viewed from behind showing four pulmonary veins entering into a vertical confluence behind the left atrium, which is drained by a large descending vein entering into the hepatic venous system. The descending vein is narrowed as it crosses the diaphragm and the hepatic veins, with which it communicates, are dilated.

Pulmonary vascular resistance

Pulmonary blood flow increases rapidly at birth as PVR falls. This normal process will have adverse effects if an increase in pulmonary venous return is disadvantageous. As discussed above, this can happen in the presence of pulmonary venous obstruction from any cause or if exit of blood from the left atrium is impeded. Increased pulmonary blood flow secondary to lesions allowing left-to-right shunting will cause respiratory distress and heart failure as PVR falls. This usually is not a problem in the early newborn phase and often is not apparent until 2 or 3 months of age. A common exception to this statement is patent ductus arteriosus (PDA) in the preterm infant (see below). Any shunt lesion may become symptomatic at an earlier postnatal age in preterm infants than in term ones; this is attributed to less well-developed pulmonary vascular musculature in the premature infant (Heymann 1995). It is also probable that widespread use of more effective mechanical ventilation and the use of surfactant may improve oxygenation, facilitating the decrease in PVR and contributing to the pathophysiological effects of a patent arterial duct in premature newborns.

Delay in the normal fall in PVR may quickly result in a clinical problem (persistent pulmonary hypertension of the newborn, PPHN). It may also play a role in the pathophysiology of chronic lung disease (CLD) and in the development of pulmonary vascular disease (PVD) in structural heart lesions, owing to unrestricted transmission of systemic pressures into the pulmonary circulation, as occurs in a large VSD or a complete atrioventricular septal defect (AVSD).

PPHN may also be seen when there has been underdevelopment of the pulmonary vascular tree in utero (such as in diaphragmatic hernia) or if there has been in utero exposure to prostaglandin synthetase inhibitors as a result of maternal therapy. Hypoxaemia in PPHN is due to right-to-left shunting, which can be either within the lungs or extrapulmonary, in which case it can be at ductal level or intracardiac through the foramen ovale.

History and examination

These are basic in the evaluation of a newborn infant with suspected cardiac disease. History-taking involves details of the current problems as well as obtaining information about pregnancy, the perinatal period, the family and social circumstances. Examination of the newborn is dealt with in Chapter 14; a number of additional points with specific reference to the cardiovascular system will be considered here.

Dysmorphic features and non-cardiac malformations

These must be carefully sought and described in detail in relation to all body systems. They are clearly important if a syndrome is to be diagnosed and may influence treatment plans and prognostic information given to families. It may be relevant to investigate other systems on the basis of certain cardiac diagnoses, for example chromosome analysis or immunological assessment. In some circumstances, recognition of an abnormality in an infant will result in a diagnosis being made in a parent, for example 22q11 deletion or Noonan syndrome. When certain non-cardiac structural abnormalities are recognised, a detailed cardiac evaluation is appropriate, as in Down syndrome and many gastrointestinal abnormalities (Tulloh et al. 1994). Of all children with chromosomal abnormalities, at least 30% have a congenital cardiac defect (Pierpoint and Moller 1987).

Pulses

Impalpable or weak femoral pulses in the presence of good-volume upper limb pulses suggest coarctation of the aorta, in which case other signs may well be present and might include upper limb hypertension, systolic pressure difference between arms and legs, evidence of aortic valve abnormality (ejection click), a bruit between the scapulae and signs of heart failure. If all pulses are weak, then left ventricular outflow obstruction, hypovolaemia or left ventricular dysfunction should be considered. Hypoplastic left heart may be associated with stronger femoral than right brachial pulses before the DA closes. A preterm infant severely compromised by PDA may have very weak femoral pulses. A baby with interrupted aortic arch usually collapses in the first week of life; the diagnosis and the site of interruption can sometimes be deduced by comparing arm and neck pulses as they will be much stronger proximal to the interruption.

Blood pressure

Blood pressure (BP) should be measured in both arms and in one leg in any newborn infant with cardiac symptoms and in an asymptomatic infant if other signs raise the possibility of coarctation. A difference in systolic BP of 20 mmHg or more between arm and leg is strongly suggestive of coarctation, although smaller gradients in term babies can be normal and the absence of such a difference may not rule out the diagnosis of coarctation if the DA is still patent. BP should also be measured in any unwell baby, as well as in those with urinary tract abnormalities, those on steroids, in CLD and in the infants of drug-addicted mothers. It is essential that the baby is settled; results on crying babies are misleading. Monitoring BP is part of the management of severely ill babies and this should be carried out invasively wherever possible. Obtaining a definitive non-invasive BP requires patience and attention to detail. The arterial pulse can be detected by palpation or with a Doppler probe. Both methods will only give a systolic value. Auscultation is very difficult and the flush method is rarely used. Oscillometric monitors may be useful in sequential BP monitoring of immobile babies but even then are subject to error at low pressures in infants with extremely low birthweight. Cuff size is important and for the arm it should cover 75% of the distance from axilla to elbow or have a width that is 40–50% of the arm circumference ([National Institutes of Health 1987](#)). The bladder should virtually encircle the arm. Leg BP can be measured using the same cuff around the calf with detection of a dorsalis pedis or posterior tibial pulse. Normal BP values are given in [Appendix 4](#).

Cyanosis

Peripheral cyanosis is very common in normal newborn babies. Central cyanosis in the presence of structural cardiac disease is caused by three main mechanisms, which may coexist. The commonest is obstruction to pulmonary blood flow with a right-to-left shunt. Cyanosis is also evident when there are discordant ventriculo-arterial connections (as in transposition) with adverse streaming of blood within the heart. Thirdly, cyanosis will also occur where there is common mixing of blood, which can occur at atrial, ventricular or great artery level, allowing the mixed systemic and pulmonary venous return to be distributed to both the aorta and the pulmonary arteries.

Central cyanosis in the neonate may have a respiratory cause but can also be mimicked by facial petechiae (traumatic cyanosis) and can be seen in markedly polycythaemic infants. Plethoric infants with a low normal oxygen saturation may have enough

Table 28.6 Features of neonatal heart failure

Acute cardiorespiratory collapse
Respiratory distress, added sounds in chest
Tachycardia (unless cause of failure is heart block)
Hepatomegaly
Poor peripheral perfusion, clammy mottled skin, cold sweatiness
Oedema – usually late but characteristic of fetal heart failure (hydrops) often with pericardial, pleural and peritoneal fluid
Excess or unexpected weight gain
Poor feeding and slow weight gain in compensated heart failure
Specific signs of causative lesion

deoxygenated haemoglobin to give true central cyanosis. Pigmentation of the lips can also confuse the observer and it is important to look at the tongue to get the best possible assessment of saturation. Anaemia and desaturation make a baby look pale grey rather than really blue, and methaemoglobinaemia gives babies a slate black or grey colour which is often mistaken for cyanosis. Cyanotic, often termed 'dusky', episodes are very common and are only occasionally a presenting feature for structural heart disease; persistent cyanosis is far more likely to be cardiac, although it may vary in intensity. Cyanosis whilst crying is rarely pathological if colour and behaviour return to normal rapidly when the infant stops crying. Hypercyanotic episodes, as seen in tetralogy of Fallot and related conditions, are rare in the newborn period.

Heart failure

Fetal echo has shown that prenatal cardiac failure can be caused by myocardial dysfunction, structural abnormalities and arrhythmias. In newborns, early heart failure usually results from myocardial dysfunction, left-heart obstructive lesions, tachyarrhythmias and large arteriovenous malformations (AVMs). These result in tachycardia, tachypnoea with recession, liver enlargement and cardiomegaly. These conditions are a medical emergency. With advancing age, lesions that cause a large left-to-right shunt are the most frequent cause of heart failure (large VSD or big PDA). They manifest as PVR falls and signs appear more quickly when there are combinations of lesions. The signs of heart failure in the older neonate are subtly different, with poor feeding, slow weight gain and tachypnoea being the most common. Common features of neonatal heart failure are listed in [Table 28.6](#).

Heart murmur

Heart murmurs in the newborn are common, occurring in up to 0.6% of newborns ([Ainsworth et al. 1999](#)). They may be associated with both major and minor cardiac lesions but also can be a normal physiological finding. Many serious cardiac conditions have unimpressive or even no murmurs in the newborn period. Other auscultatory and general cardiovascular signs are therefore very important in assessing the significance of a murmur. The absence of any other features of cardiac disease as well as the presence of certain positive murmur characteristics are required to diagnose innocent heart murmurs. The typical heart murmur in newborn babies comes from the pulmonary artery branches and disappears before 6 months of age in term infants. In practice, cardiac murmurs in the newborn that are associated with additional cardiac symptoms or signs justify prompt echocardiographic assessment unless the diagnosis has been documented prenatally, in which case knowledge of the diagnosis and clinical assessment should determine the timing of

investigation. Asymptomatic murmurs will almost always need formal investigation with echocardiography but this can usually be undertaken on an elective basis.

Airway obstruction

This uncommon presentation is usually associated with inspiratory stridor. When associated with a structural cardiac abnormality, the manifestations are usually caused by a vascular ring such as a pulmonary artery sling or a double aortic arch. Major airway obstruction can occur as part of the absent pulmonary valve syndrome in association with tetralogy of Fallot.

Investigations

History and examination often allow cardiac disease to be suspected or ruled out. Investigations range from those readily available in any neonatal nursery (chest X-ray (CXR; [Ch. 27 part 2](#)), electrocardiogram (ECG), pulse oximetry and hyperoxia test) to those only available at cardiac centres (cardiac catheterisation and magnetic resonance imaging (MRI)). Echocardiography is being increasingly used outside cardiac centres and, with suitable equipment and trained operators, is very valuable in the care of the newborn, particularly to confirm or rule out a cardiac abnormality in those cases where clinical assessment, ECG and CXR have been inconclusive. The value of ECG and CXR in differentiating normal from abnormal murmurs in the newborn has not been systematically examined, and they are less often used now. The role of pulse oximetry as a screening test is also discussed below.

Chest radiography

CXR is less valuable in the newborn period in the evaluation of CHD because the appearance can be normal even in the presence of a severe congenital cardiac malformation. Its value lies in its availability, cost and the additional information it provides. Visceral situs, cardiac position, cardiac size and bony abnormalities of the chest are all well seen on the CXR. Features to look for in this context are listed in [Table 28.7](#); examples are shown in [Figures 28.3–28.6](#) and see [Ch. 43](#). The role of the CXR has diminished with the more widespread use of transthoracic echocardiography.

Electrocardiogram

The ECG provides useful information in a number of areas ([Table 28.8](#)), providing attention is paid to technical aspects of obtaining a good recording, which can be difficult in a neonatal nursery. Systematic reading of the ECG will optimise the information obtained and reference should be made to normal values ([Appendix 3](#)) and to a standard text for detailed interpretation of ECGs ([Park and Guntheroth 1992](#)).

Heart rhythm

Abnormal heart rate can be confirmed on the ECG and heart rhythm can usually be ascertained. Sinus rhythm is characterised by normal P waves (frontal plane axis 0–190°) preceding every QRS complex. Sinus rate varies between 70 and 180 beats/min in healthy babies, reaching as much as 220 beats/min in sick babies. In these circumstances, P waves can be hard to see but all leads should be examined and paper run at a faster speed (50 mm/s) if necessary. First-degree heart block (prolonged PR interval) is rarely of importance in its own right in the newborn but may be a marker for structural heart

Table 28.7 Features of suspected cardiac disease

FEATURE	COMMENT
Quality of film	Adequate inspiration Normal penetration Centred on midchest Not rotated
Abdominal situs	
Bronchial situs	Normal/inverted/ambiguous
Aortic arch side	Left or right
Heart	Side Direction of apex Size Contour
Lung vasculature	Plethora Oligaemia Pulmonary venous engorgement
Diaphragm	Distinct Side of apex should be more caudal
Lung fields	Any pathology
Musculoskeletal	Vertebral/rib abnormalities Fractures

Table 28.8 Information obtainable from the electrocardiogram

– Hypertrophy
– Strain/ischaemia

disease such as ASD or Ebstein's anomaly. A short PR interval is a marker for an increased tendency to supraventricular tachycardia (SVT), although delta waves in the QRS complex may easily be overlooked in neonates. A short PR interval also accompanies some structural heart lesions (Ebstein's anomaly) and may be seen in glycogen storage disease. Partial atrioventricular (AV) dissociation (second-degree heart block) and complete heart block (CHB) are considered below, as are SVT and ventricular tachycardia (VT).

Information on the atria

Inverted P waves in lead I may be a sign of an incorrectly wired ECG (right arm/left arm reversed). This can be checked by looking at lead V₆. If I and V₆ look similar, the ECG is wired up correctly and negative P waves in I then suggest one of the following:

- not sinus rhythm ([Fig. 28.7](#))
- heart in abnormal position
- heart in normal position but atria in abnormal spatial relationship to each other.

Fig. 28.3 Posteroanterior chest X-ray showing marked cardiomegaly with pulmonary plethora in association with congestive cardiac failure.

Fig. 28.4 Posteroanterior chest X-ray showing normal abdominal situs with dextrocardia.

Fig. 28.5 Posteroanterior chest X-ray showing abdominal situs inversus with a midline liver and dextrocardia.

Fig. 28.6 Posteroanterior chest X-ray showing massive cardiomegaly in a neonate with severe Ebstein's anomaly.

Fig. 28.7 Electrocardiogram leads I, II and III, showing inverted P wave in I. Supraventricular tachycardia at 190 beats/min.

Right atrial enlargement is indicated by tall (>2.5 mV) P waves and left atrial enlargement shown by broad (<3 mm) P waves at standard paper speed (25 mm/s).

Information on the ventricles

Abnormal ventricular positions within the chest, as in dextrocardia, or in relationship to each other, as in congenitally corrected transposition, can be suspected from abnormalities in QRS progression across the chest leads. In dextrocardia, complexes do not evolve between V_1 and V_6 but simply get progressively smaller. Q waves in V_1 mean one of the following:

- abnormal intraventricular conduction (as in left bundle branch block or some cases of pre-excitation)
- severe RV hypertrophy (RVH)
- spatial relationship between right and left ventricles abnormal (as in congenitally corrected transposition).

RVH is suggested by one or more of the following:

- right axis deviation
- Q in V_1
- large RV_1 or SV_6 (Appendix 3)
- upright T in V_1 after day 3 (Fig. 28.8).

It is important to note that conditions causing marked RVH in later infancy may cause no ECG abnormality in the immediate newborn period and only an upright T wave in V_1 in the later newborn period.

Left ventricular hypertrophy is suggested by one or more of the following:

Fig. 28.8 Electrocardiogram chest leads in a 6-day-old infant. Neonatal R→S progression (normal) but upright T-wave V_1 indicating right ventricular hypertrophy.

- adult R/S progression V_1 to V_6 (dominant SV_1 dominant RV_6)
- large SV_1 or RV_6 (Appendix 3).

Biventricular hypertrophy is indicated by a combination of these findings.

Ventricular strain or ischaemia is indicated by ST depression or T-wave inversion in left chest leads (II, aVL, V_{5-6}) and may point to a primary cardiac muscle disorder or be secondary to a severe structural abnormality causing pressure or volume load on the heart. T-wave changes are seen after perinatal stress and resolve in under a week. Pericarditis is rare in the newborn period but ST segment and T-wave changes are seen.

QRS axis

The frontal QRS axis can be calculated as shown in Figure 28.9. An abnormal QRS axis may be an important diagnostic clue in a number of conditions, including AVSD (Fig. 28.10) and tricuspid atresia (QRS usually -30°); in the former case it makes the ECG a valuable screening investigation in newborn infants with Down syndrome, in whom clinical features of AVSD may be absent or very subtle.

Fig. 28.9 Electrocardiogram standard leads, superior QRS axis (-90°), newborn with complete atrioventricular septal defect.

Pulse oximetry

Pulse oximetry has been advocated as a screening tool for CHD in newborns. Because newborns with complex CHD will often deteriorate within 48 hours of age, oximetry would be performed ideally within 24 hours of birth. However, saturations in newborns vary considerably during the first 24 hours, which can increase the false-positive rate. Most healthy newborns are now discharged before 24 hours of age, which limits the use of this technique. Oximetry should be performed on the foot of a baby breathing air. A value of less than 95% is found in about 5% of apparently well infants (Richmond et al. 2002). If these infants are further evaluated (by repeating the test initially), few cases of important structural heart disease are overlooked and some other potentially unwell infants are also detected. The American Heart Association and American Academy of Pediatrics have recently reviewed the question of pulse oximetry screening after 24 hours of age in some detail (Mahle et al. 2009). Ten studies with a population of 123 846 infants were summarised, with a false-positive rate of 0.035% when screening was done after 24 hours. Most studies used a cut-off of 95%. The detection rate for many conditions was good, but the authors conclude that additional studies are needed to determine whether this practice should become a standard of care.

Hyperoxia test and blood gas analysis

The hyperoxia (or nitrogen washout) test was described in the era before echocardiography was available and was designed to help distinguish cardiac from respiratory cyanosis without resorting to cardiac catheterisation. Babies with cyanotic heart disease usually show little rise in arterial oxygen tension in response to increased inspired oxygen. A rise of P_{aO_2} to a value below 20 kPa after 10 minutes in 85% or more inspired oxygen makes heart disease likely, whereas an increase in P_{aO_2} above 20 kPa makes respiratory disease

Fig. 28.10 Hexaxial reference system for calculating the frontal plane axis of the QRS complex (and of P and T waves if required). The frontal axis of the QRS complex can be estimated from the diagram showing polarity of electrocardiogram leads I, II, III, aVL, aVF and aVR. To obtain the frontal axis of a QRS complex:

1. Identify the lead in which the R and S waves are most nearly of equal size.
2. Look at right angles (190° and 290°) to the lead identified in step 1.
3. One of the leads identified in step 2 will be predominantly positive, the other predominantly negative.
4. The predominantly positive lead identified by step 3 is approximately the QRS axis (depolarisation towards a lead produces a positive deflection).
5. The approximate QRS axis obtained from step 4 can be made more accurate by estimating the equiphase lead (step 2) more accurately by 'imagining' it between actual leads.

If all leads appear equiphase, the QRS axis is described as indeterminate; this is rarely normal.

likely. There are some exceptions to this pattern in that babies with desaturating cardiac disease with high lung blood flow (as in unobstructed TAPVC and double-inlet ventricle, for example) will pass, whereas those with very severe respiratory disease and with PPHN may fail.

When it is essential to have an accurate measurement of arterial oxygen content, an arterial blood sample must be obtained, and further information of importance in the management of ill infants will also be available from a blood gas analysis. Transcutaneous oxygen tension monitors placed on the right upper chest (that is, preductal) can be used instead of arterial sampling as a screening test if other information is not required. Oxygen pulse saturation monitors will not provide the same assurance of a pass, as an infant will show 100% saturation at a P_{aO_2} value well below 20 kPa. The role of the hyperoxia test has therefore changed since its inception, but it is still helpful in two circumstances:

1. When a well baby seems dusky and there is uncertainty as to whether a cyanotic cardiac condition is present. A failed transcutaneous or pulse oximeter hyperoxia test strongly points to cyanotic heart disease.
2. A well baby with signs of heart disease who looks pink may fail the hyperoxia test, thus alerting the physician to the presence of a more complex lesion.

Echocardiography

Transthoracic echocardiography has revolutionised the diagnosis and management of neonatal heart disease. The non-invasive, immediate and portable nature makes this modality ideally suited to the investigation of even the smallest babies. It can define structure and function and has resulted in a dramatic reduction in the need for diagnostic cardiac catheterisation. It is now widely used to guide interventions such as balloon atrial septostomy on the intensive care unit.

The sequential and segmental approach forms the basis of diagnosis of all CHD. A detailed description of this is beyond the scope of this chapter but can be found in [Anderson et al. \(2002\)](#). This systematic approach ensures that subtle complex problems are not overlooked even in the most complex malformations. All examinations should begin with indirect evaluation of atrial situs using the great vessels at the level of the diaphragm ([Figs 28.11 and 28.12](#)). This is followed by establishing the position of the cardiac apex in the chest from a subcostal view. The same echocardiographic window allows identification of the systemic and pulmonary venous drainage and evaluation of the atrial septum. This is followed by establishing the AV connection and assessment of the AV valves. Next, the position and morphology of the ventricles are established and the ventricular septum is assessed; this is most easily viewed from the cardiac apex. Following this, the ventriculoatrial connections are documented together with the relationship of the great arteries. Assessment of the semilunar valves is followed by documentation of the coronary arteries. From the parasternal views, the branch pulmonary arteries are identified and the aortic arch with the head and neck vessels seen from the suprasternal position. Finally, assessment of function is evaluated using m-mode from a parasternal long-axis view.

Table 28.9 Uses of different ultrasound modalities

MODALITY	USES
Two-dimensional imaging	Defining anatomy Chamber size, wall thickness Function (qualitative)
Doppler	Assessment of direction and velocity of flow, turbulence and flow patterns
Colour flow	Rapid identification of site of abnormal flow patterns and flow direction Detection of regurgitation and small shunts
Pulsed wave	Sampling flow patterns in a localised region May be inaccurate with high velocities Calculation of cardiac output
Continuous wave	Excellent for high velocities Abnormal flow patterns not precisely localised
M mode	Dimensions and function

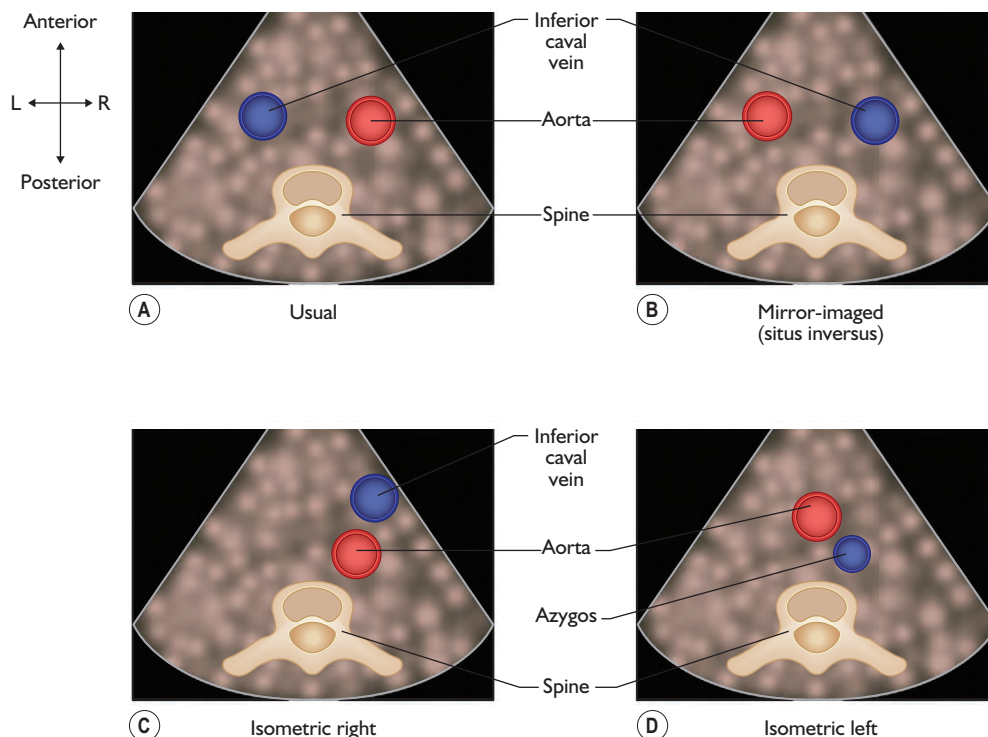

Fig. 28.11 Diagrammatic representation of echocardiographic images of arrangement of great vessels at the level of the diaphragm in: (A) normal atrial situs, (B) mirror-imaged arrangement, (C) right and (D) left atrial isomerism.

Fig. 28.12 Schematic representation of: (A) normal situs, (B) mirror-imaged arrangement, (C) right and (D) left atrial isomerism.

All ultrasound modalities have a role in evaluating the cardiovascular system (Table 28.9). Newer ultrasound modalities such as three-dimensional and four-dimensional imaging as well as new Doppler techniques including Doppler tissue imaging and strain imaging are becoming more widely used in the management of CHD but have limited applications in routine neonatal practice at present. More detailed descriptions of these techniques are found in other sources (Mertens et al. 2008).

Standard two-dimensional imaging gives anatomical detail. Doppler identifies or clarifies shunt lesions and regions of turbulent flow and allows quantification of stenosis by measuring blood velocity. This enables calculation of a pressure difference across a valve or between ventricles through a VSD using the modified Bernoulli equation ($P = 4V^2$, where P = instantaneous peak systolic pressure gradient in mmHg, V = velocity distal to the site of obstruction in m/s).

Standard echocardiographic windows and images of the heart are shown in Figure 28.13; examples of clinical scans are given in Figures 28.14–28.16. Transthoracic echocardiograms may be technically difficult in babies with severe respiratory disease on assisted ventilation. Many of these infants are premature and

of low birthweight. As echocardiographic skills become more widespread, telemedicine provides the means whereby neonatal units can collaborate with cardiac centres to analyse recorded echocardiographic studies, helping in the decision-making about whether a baby needs transfer to a tertiary cardiac unit (Casey 1999).

Cardiac catheterisation

Cardiac catheterisation and angiography was once the principal means of investigating babies with CHD. It may be diagnostic for anatomical or haemodynamic information or may be therapeutic. Diagnostic catheterisation is now rarely required in the newborn baby with present-day ultrasound capability and other non-invasive imaging modalities. When it is, usually only a small amount of information is required in order to complement that already obtained by echocardiography. Cardiac catheterisation in small children carries a small but definite risk and almost inevitably requires general anaesthesia. This will influence cardiac physiology and the relevance of the information obtained.

Fig. 28.13 (A) Diagram illustrating echocardiographic cross-sectional planes (two-dimensional). The long-axis plane is approximately sagittal; the four-chambers plane is approximately frontal; the short-axis plane is approximately transverse. (B–F) Diagrammatic representations of normal, cross-sectional views. (B) Long-axis cut as seen with the transducer in the parasternal position. (C) Four-chambers cut as seen from the subxiphoid site. (D) Semi-long-axis cut of the aortic arch as obtained from the suprasternal view. (E) High long-axis cut (parasagittal) to show the ductus arteriosus. (F) Short-axis cut through the great arteries just above the heart. Ao, aorta; Dao, descending aorta; Fo, foramen ovale; LA, left atrium; lpa, left pulmonary artery; LV, left ventricle; m, mitral valve leaflets; PA, pulmonary artery; RA, right atrium; rpa, right pulmonary artery; RV, right ventricle; svc, superior vena cava; t, tricuspid valve leaflets. (Reproduced from Wilkinson and Cooke 1992.)

Fig. 28.14 (A) Apical four-chamber view showing small mid-muscular ventricular septal defect (VSD). (B) Apical four-chamber view of an atrioventricular septal defect with a common atrioventricular valve orifice (CAVVO) and moderate atrial and ventricular components. The ventricles are balanced. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (C) Apical four-chamber view showing small hypertrophied right ventricle with small tricuspid valve in a patient with pulmonary atresia and intact ventricular septum (hypoplastic right heart). (D) Apical four-chamber view showing hypoplastic left-heart syndrome with small hypertrophied left ventricle (see Fig. 28.20). (E) Apical four-chamber view of double-inlet left ventricle with VSD and hypoplastic right ventricle.

Fig. 28.14, cont'd (F) Apical four-chamber view of dilated cardiomyopathy with severe left atrial and left ventricular dilatation. Mitral regurgitation is seen on colour flow mapping.

Magnetic resonance and computed tomographic imaging

MRI provides excellent anatomical images, but, in the newborn, echocardiography often provides adequate information. The range of uses for cardiac MRI scanning in the newborn is continuing to expand as greater experience is obtained in older children and scanning technology improves. It can provide useful non-invasive anatomical information about pulmonary arterial abnormalities previously only obtainable from angiography. MRI involves no radiation hazard, but does require sedation or general anaesthesia in an environment where detailed monitoring is rather more complicated to achieve. In contrast, computed tomographic (CT) imaging, which requires shorter acquisition times and can frequently be performed with sedation alone, does have a role as a non-invasive imaging technique in neonates. It provides excellent information about aortic arch anatomy and other vascular structures (Fig. 28.17) and the relationship of the vascular structures to the airways but its drawback is the radiation dose required to acquire such images.

Treatment

General principles

In principle, medical management for CHD is largely supportive (e.g. heart failure) whereas significant structural abnormalities usually require intervention. Continued improvement in surgical results for congenital cardiac malformations has been one of the triumphs of modern paediatric cardiology. Surgical mortality for malformations, which were, up to recently, considered untreatable (e.g. hypoplastic left-heart syndrome (HLHS)) is now very acceptable. In addition, improvements in surgical results have meant a

major shift in surgical emphasis away from surgical palliation towards primary neonatal correction of structural abnormalities with restoration of normal physiology wherever possible. This has been further facilitated by the advances occurring in neonatal intensive care both pre- and postoperatively.

Attention to the general aspects of medical care to achieve stability and optimise condition prior to transfer and intervention of any kind is a very important aspect of minimising morbidity and mortality for any cardiac condition. There are some specific areas related to the care of neonates with cardiac disease that require further mention.

Ductal manipulation

Establishing and maintaining an open DA is a crucial part of the resuscitation of babies with duct-dependent pulmonary or systemic circulations and usually greatly improves oxygenation in TGA. Prostaglandin E_1 and E_2 will both dilate the DA. Dosage regimens for both drugs are given in Table 28.10. Acute side-effects of prostaglandin include apnoea, jitteriness, convulsions, diarrhoea, flushing and fever and are dose-dependent. These are usually manageable without loss of therapeutic effect by stopping the infusion for a few minutes and restarting it at a lower dose. Long-term oral or nasogastric use is described (Silove *et al.* 1985) but of limited value. Manipulation of the DA in order to close it is considered on pages 645–647.

Heart failure

Management of heart failure is outlined in Table 28.11. Treatment of acute heart failure is considered under collapse, below. On a more chronic basis, minimising fluid restriction is necessary to achieve as good a nutritional state as possible. It is usually possible

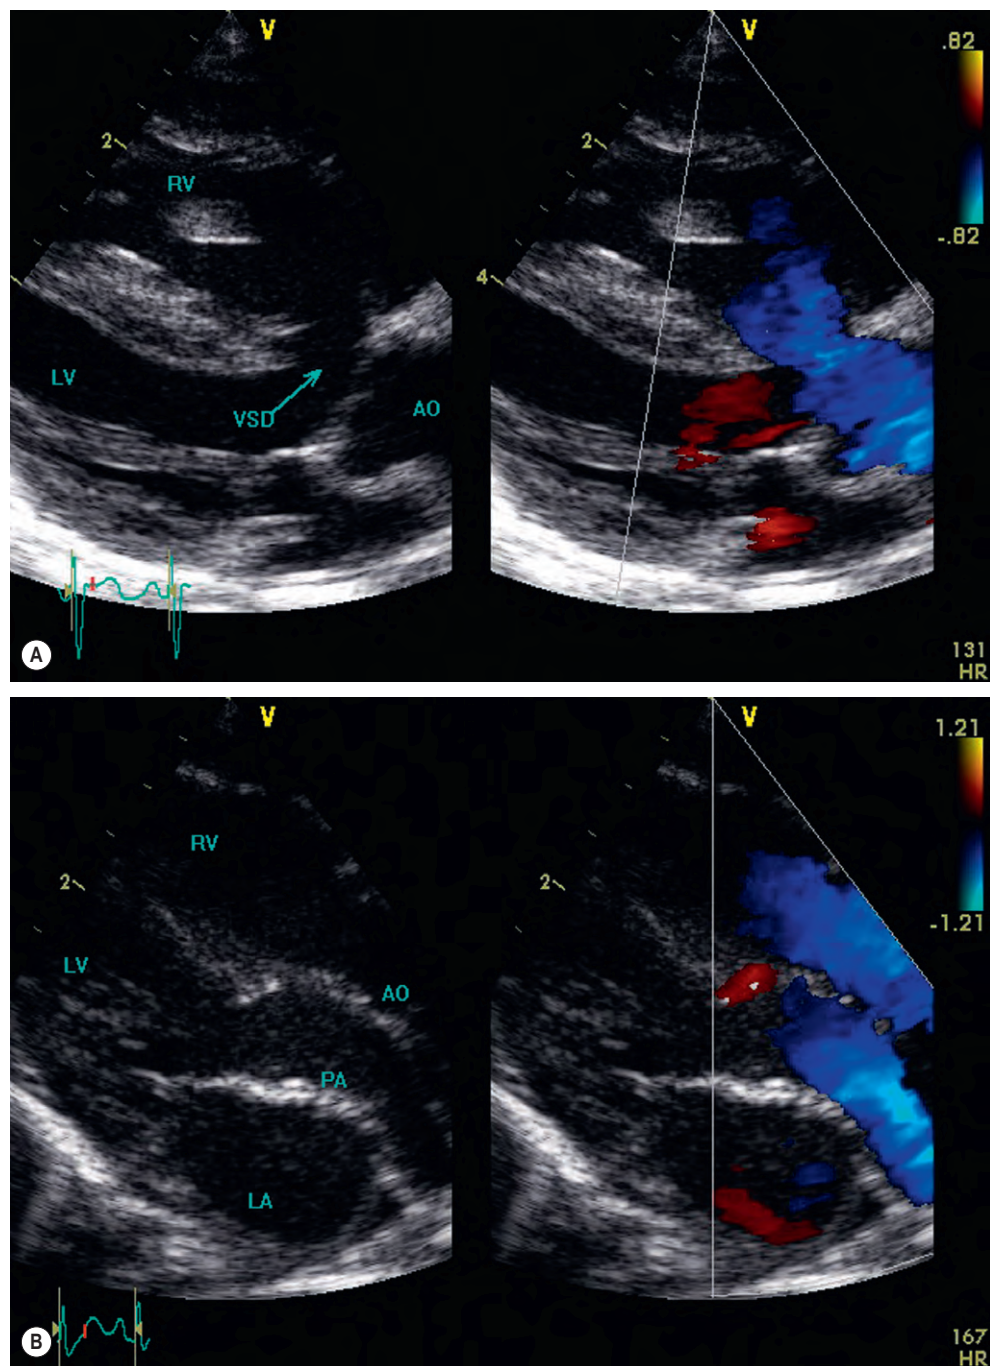

Fig. 28.15 (A) Parasternal long-axis view of a patient with tetralogy of Fallot showing subaortic ventricular septal defect. Note the flow from right ventricle to aorta seen on the colour flow mapping. Ao, aorta; LV, left ventricle; RV, right ventricle; VSD, ventricular septal defect. (B) Parasternal long-axis view showing diagnostic arrangement of the great vessels in transposition of the great arteries, which have a parallel arrangement as they arise from their respective ventricles. Ao, aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RV, right ventricle.

Fig. 28.15, cont'd (C) Subcostal four-chamber view of the atrial septum showing large secundum atrial septal defect with left-to-right flow seen on colour flow mapping. ASD, atrial septal defect; LA, left atrium; RA, right atrium; SVC, superior vena cava. (D) Suprasternal view showing aortic arch with coarctation. Narrowed area of aortic arch highlighted with flow disturbance seen on colour flow mapping.

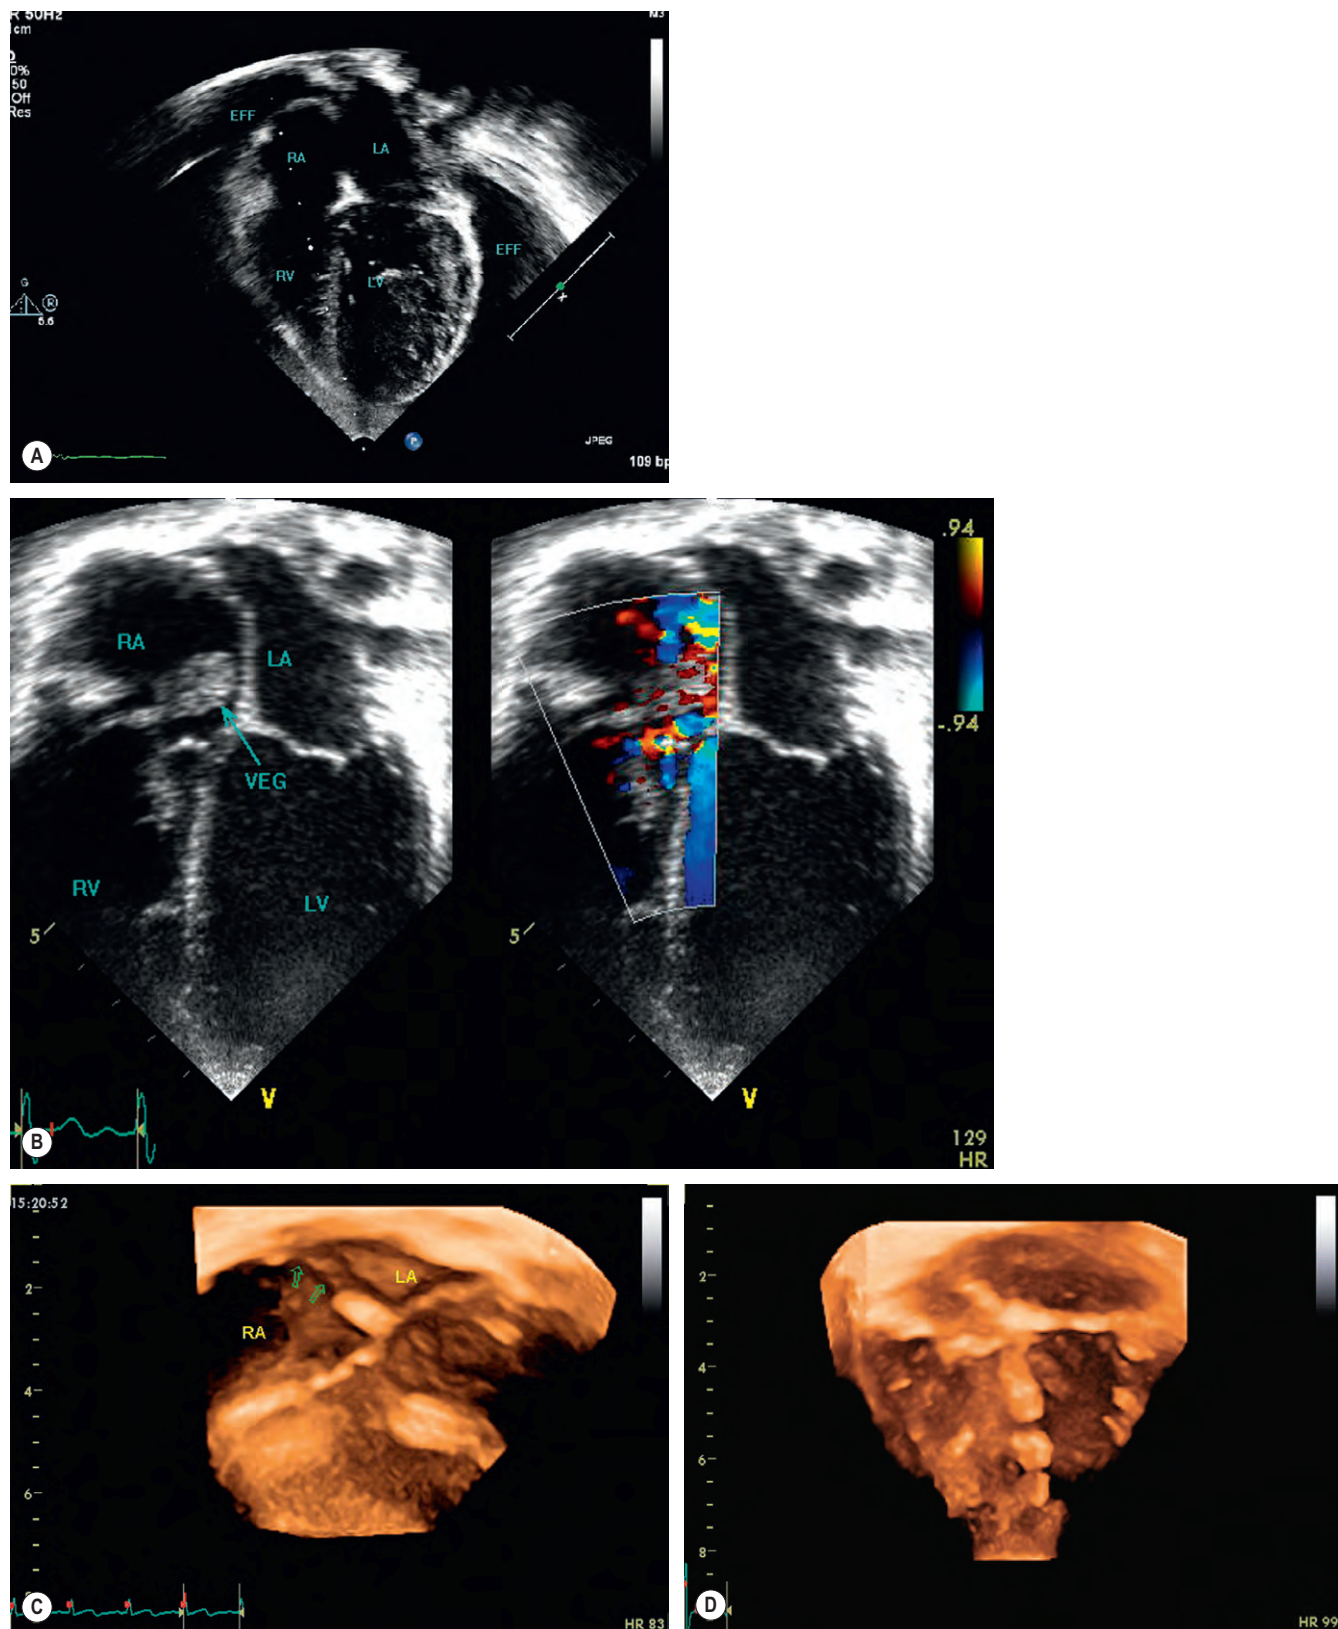

Fig. 28.16 (A) Apical four-chamber view showing global pericardial effusion (EFF, effusion). (B) Apical four-chamber view showing tricuspid valve vegetation in bacterial endocarditis (VEG, vegetation). Colour flow mapping shows moderate tricuspid regurgitation associated with the vegetation. (C) Volume-rendered three-dimensional echo image of a secundum atrial septal defect seen from the subcostal projection. (D) Volume-rendered three-dimensional echo image of multiple apical muscular ventricular septal defects seen in a four-chamber projection. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

Fig. 28.17 (A) Volume-rendered computed tomography angiogram (anterior view) showing a right-sided aortic arch with aberrant left subclavian artery (LSCA). (B) Same image (posterior view). This aortic arch anatomy is usually associated with a left-sided arterial duct arising adjacent to the origin of the aberrant left subclavian artery creating a loose vascular ring. (C) Axial contrast-enhanced image, in the same patient, showing a right-sided arch with the origin of LSCA arising posterior to the trachea.

to regulate fluid status with diuretics and allow a good volume intake. Additives to increase the calorific value of milk are almost invariably needed and nasogastric feeding may be required. Loop diuretics may cause hyponatraemia, necessitating a reduction of dose with modest fluid restriction if necessary or changing to thiazide diuretics. Monitoring of serum sodium is an important part of managing heart failure in neonates on diuretics but increasing sodium supplements in this context is to be avoided if possible, as this will also cause fluid retention. There is considerable experience of angiotensin-converting enzyme (ACE) inhibitor usage in infancy (Montigny et al. 1989). There are greater risks in the use of ACE inhibitors in newborns (Lee et al. 2010) and preterm newborns appear to tolerate ACE inhibition poorly. If an ACE inhibitor is to

be used, it is important to ensure that renal function is normal, avoid dehydration with diuretics before commencing the drug and increase the dosage gradually to therapeutic levels. Digoxin may be of value in chronic heart failure associated with poor muscle function, but neither drug should be used when dynamic left ventricular outflow obstruction is present.

Antiarrhythmic drugs

Arrhythmias and their management are considered on pages 661–663. Doses of commonly used antiarrhythmic agents are given in Table 28.28.

Table 28.10 Prostaglandin (PG) dosage regimens

DRUG AND ROUTE	DOSE	COMMENT
PGE ₁ i.v.	0.005–0.1 µg/kg/min	For severe cyanosis or shock, start at higher dose range for both drugs and increase at 15–30-minute intervals to maximum if no response. More than threefold increase in dose rarely needed. Side-effects increase with higher doses
PGE ₂ i.v.	0.005–0.05 µg/kg/min	
NB. In antenatally diagnosed duct-dependent congenital heart disease, elective prostaglandin infusion should be started at the lowest dose (5–10 ng/kg/min) as this will minimise side-effects whilst maintaining ductal patency.		

Interventional catheterisation

There has been a spectacular increase in the range of interventional catheter techniques for the management of congenital cardiac malformations. Therapeutic catheterisation for some procedures can be performed under ultrasound control, such as for balloon septostomy, but more complex therapeutic interventions usually require X-ray screening. Conditions treated in the newborn period by interventional cardiac catheterisation are listed in [Table 28.12](#). The range of conditions amenable to interventional cardiac catheterisation in the newborn continues to expand (e.g. stenting of PDA or RV outflow in pulmonary atresia or severe tetralogy of Fallot), complementing surgical advances and sometimes avoiding the need for surgery in low-birthweight infants. Development of hybrid interventional catheter and surgical procedures is also increasing, with first-stage palliation of HLHS being the most well-developed example ([Galantowicz et al. 2008](#)).

Vascular access can be obtained via the umbilicus or percutaneously in the femoral region. Babies will invariably require general anaesthesia, and extra attention to body temperature, blood glucose, circulating volume, acid–base balance and ventilation is necessary to ensure that risk of the procedure is minimised. Mortality in diagnostic and interventional catheterisation in the newborn is less than 1%, but acute morbidity may occur in up to 25% of interventional procedures. This area is changing all the time and choosing between surgical and catheter interventions for the same condition is influenced by many factors ([Andrews and Tulloh 2004](#)).

Surgery

Cardiac surgery can be subdivided into two major groups according to whether the operation requires the use of the cardiopulmonary bypass machine. Open cardiac surgery requiring cardiopulmonary bypass is used for intracardiac repairs (e.g. arterial switch operation for repair of transposition, repair of TAPVC) and also for staged palliative surgery for complex cardiac lesions (e.g. HLHS). Closed operations do not require cardiopulmonary bypass (as in coarctation repair, clipping of the DA, Blalock–Taussig systemic-to-pulmonary anastomoses and pulmonary artery banding) and the

Table 28.11 Heart failure management

ACUTE	CHRONIC
Resuscitate as needed for collapse/shock with ventilation, colloids and inotropic support	Avoid fluid restriction if possible, in order to maximise calorie intake
Restrict fluid to approximately two-thirds maintenance	Optimise calorie intake (high-calorie formula/supplements, nasogastric feeding)
Furosemide i.v. 1 mg/kg 6–12-hourly	Oral diuretic: furosemide 2–6 mg/kg/day (in two or three doses) and potassium-sparing diuretic or potassium supplement
Optimise oxygenation, avoid hyperoxia	If heart muscle dysfunction, consider angiotensin-converting enzyme inhibitor and/or digoxin
Treat anaemia	Treat anaemia if present

surgery is shorter and, for the most part, lower risk than open cardiac surgery. Open operations are generally performed through a median sternotomy whereas closed operations are more commonly performed through a posterolateral thoracotomy. Practice will vary from centre to centre but, in most centres, neonatal primary correction is the treatment of choice in simple and complex TGA, TAPVC, interrupted aortic arch and common arterial trunk. Operative mortalities are given in the discussion of particular conditions. As surgical mortality rates improve, there has been increasing awareness of the morbidity associated with complex CHD ([Limperopoulos et al. 2000](#)). Attributing such problems to individual surgical techniques (such as low-flow bypass versus deep hypothermic circulatory arrest) has failed to yield consistent results. There is increasing evidence to support a multifactorial aetiology for brain injury occurring in association with complex CHD with a significant proportion of the damage occurring preoperatively, as evidenced by detailed MRI scanning undertaken before surgery ([Miller and McQuillen 2007](#)).

Persistent pulmonary hypertension of the newborn

Therapy is considered in [Chapter 27](#), part 2.

Cardiovascular problems in the preterm infant

General considerations

The combination of CHD and prematurity adversely affects the outcome for the baby in relation to both the prematurity and for any given structural cardiac malformation. Improvements in the care of preterm infants and increased detection of fetal cardiac disease have meant an increasing number of premature, low-birthweight infants are surviving with congenital heart defects. A discussion about the patent arterial duct in the preterm infant

Table 28.12 Interventional cardiac catheterisation in newborn infants

TECHNIQUE	COMMENT
Balloon septostomy	TGA and restrictive PFO in mitral restriction or hypoplastic right heart
Balloon dilatation	
Pulmonary valve	Procedure of choice for stenosis
Aortic valve	First choice in most centres for stenosis
Coarctation	Lower success and higher complication rates than surgery
Infundibulum	Occasionally in TOF with severe RVOTO (\pm RVOT stenting)
Pulmonary atresia	Becoming widespread if no VSD Occasionally used if VSD present Radiofrequency-assisted perforation and valvuloplasty
Stent techniques	
Ductus arteriosus	As an alternative to systemic to PA shunt in some duct-dependent lesions Being explored as part of initial palliation of hypoplastic left heart
Embolisation/occlusion techniques	
Cerebral AVM	Treatment of choice for neonates in heart failure
Scimitar syndrome	For aberrant arterial supply to right or left lung
Patent arterial duct	Coil occlusion device: closure of PDA occasionally appropriate
TGA, transposition of the great arteries; PFO, patent foramen ovale; TOF, tetralogy of Fallot; RVOTO, RVOT, right ventricular outflow tract; VSD, ventricular septal defect; PA, pulmonary atresia; AVM, arteriovenous malformation; PDA, patent ductus arteriosus.	

follows but other types of structural cardiac disease deserve mention. Persisting atrial communications are common in preterm infants but do not usually cause problems unless associated with additional defects such as a large patent arterial duct. Reducing the shunt by closing the duct is often enough to avoid problems. In other defects, the baby is often too small to be considered for corrective or even palliative surgery. In babies with a large left-to-right shunt through a VSD the effects of the left-to-right shunt will frequently worsen the lung disease associated with prematurity, increasing both mortality and morbidity. Early pulmonary artery banding to reduce pulmonary blood flow is useful provided the baby is of sufficient size and is well enough to tolerate the procedure. In duct-dependent lesions, it has been possible to maintain ductal patency with prostaglandin whilst the baby grows big enough to be considered for surgical or catheter intervention (Barker et al. 2005). This is better tolerated when the pulmonary blood supply is duct-dependent rather than the systemic circulation, probably because the duct is smaller and more restrictive in the former group of patients. When the systemic circulation is duct-dependent, the duct is large and, as

PVR falls, there is steal from the systemic circulation to the pulmonary circulation. This increases the risks of necrotising enterocolitis and exacerbates the pulmonary problems associated with prematurity. Published data confirm the poor outlook in premature babies with CHD (Andrews et al. 2006).

Patent ductus arteriosus

Closure of the DA in term babies occurs in two phases. First, the increased Pao_2 which occurs within a few hours of birth, together with the decreased circulating prostaglandins, allows the smooth muscle of the DA to constrict. Constriction causes the inner muscular wall of the DA to become ischaemic and hypoxic, promoting formation of vascular endothelial growth factor, which in turn results in production of other growth factors, transforming the DA into a non-contractile ligament (Clyman et al. 1999). In preterm infants the DA will often fail to constrict, and, in those in whom constriction occurs, complete occlusion does not occur as the profound hypoxia required to achieve this fails to develop. It is the profound hypoxia that drives the inflammatory cascade that results in cell death and remodelling. In the term baby the vasa vasorum are occluded during ductal constriction, causing the hypoxia. In the preterm infant the ductus is so thin-walled that the vasa vasorum are not required for transport of oxygen and nutrients to the vessel wall. These are derived from the lumen of the ductus instead and therefore the wall of the ductus is unable to develop the hypoxia required to achieve remodelling (Clyman et al. 1999). This enables the DA to reopen with its associated haemodynamic consequences.

A persistent DA is diagnosed when the DA fails to close after 72 hours. Symptoms will develop in 50–70% of infants at <28 weeks' gestation or with a birthweight of less than 1000 g (Hammerman and Kaplan 1990). Clinical complications will depend on the degree of left-to-right shunting through the DA, which causes increased left ventricular output and a redistribution of blood flow that can result in metabolic acidosis, intracranial haemorrhage, necrotising enterocolitis and pulmonary oedema or haemorrhage (Clyman 1996). In those babies with a persistent DA, prophylactic closure of the DA would seem attractive but has been, and remains, one of the most hotly debated topics in neonatal medicine (Benitz 2010). Concern remains about administration of a drug known to have deleterious side-effects on cerebral, renal and splanchnic blood flow. Yet there is strong clinical and experimental evidence to support the fact that the efficacy of indometacin decreases with advancing postnatal age (Hermes-DeSantos and Clyman 2006). This dilemma is worsened by the fact that it is very difficult to predict which babies will go on to develop clinical complications as a result of a persistent DA. There is evidence that a DA minimum diameter on colour flow Doppler of 1.5 mm or greater in babies less than 1500 g birthweight and postnatal age less than 10 days is strongly predictive of the development of symptoms (Kluckow and Evans 1995). A left atrial to aortic root ratio of greater than 1.5 after the first day of age also helps predict problems (Iyer et al. 1994). The Doppler waveform across the ductus (Fig. 28.18B, D, F) has been used to predict development of a symptomatic DA in a similar group of babies under 5 days old (Su et al. 1997) and in managing drug treatment (Su et al. 1999). Su and colleagues (1999) identified low-velocity (not above 1.5 m/s) left-to-right shunting through the DA (termed a pulsatile pattern: Fig. 28.14D) in the first 4 days after birth in ventilated babies under 1500 g birthweight as indicating a high risk of developing symptomatic DA (sensitivity 93.5%, specificity 100%) as opposed to a closing pattern (Fig. 28.18B), which was not associated with the development of symptoms.

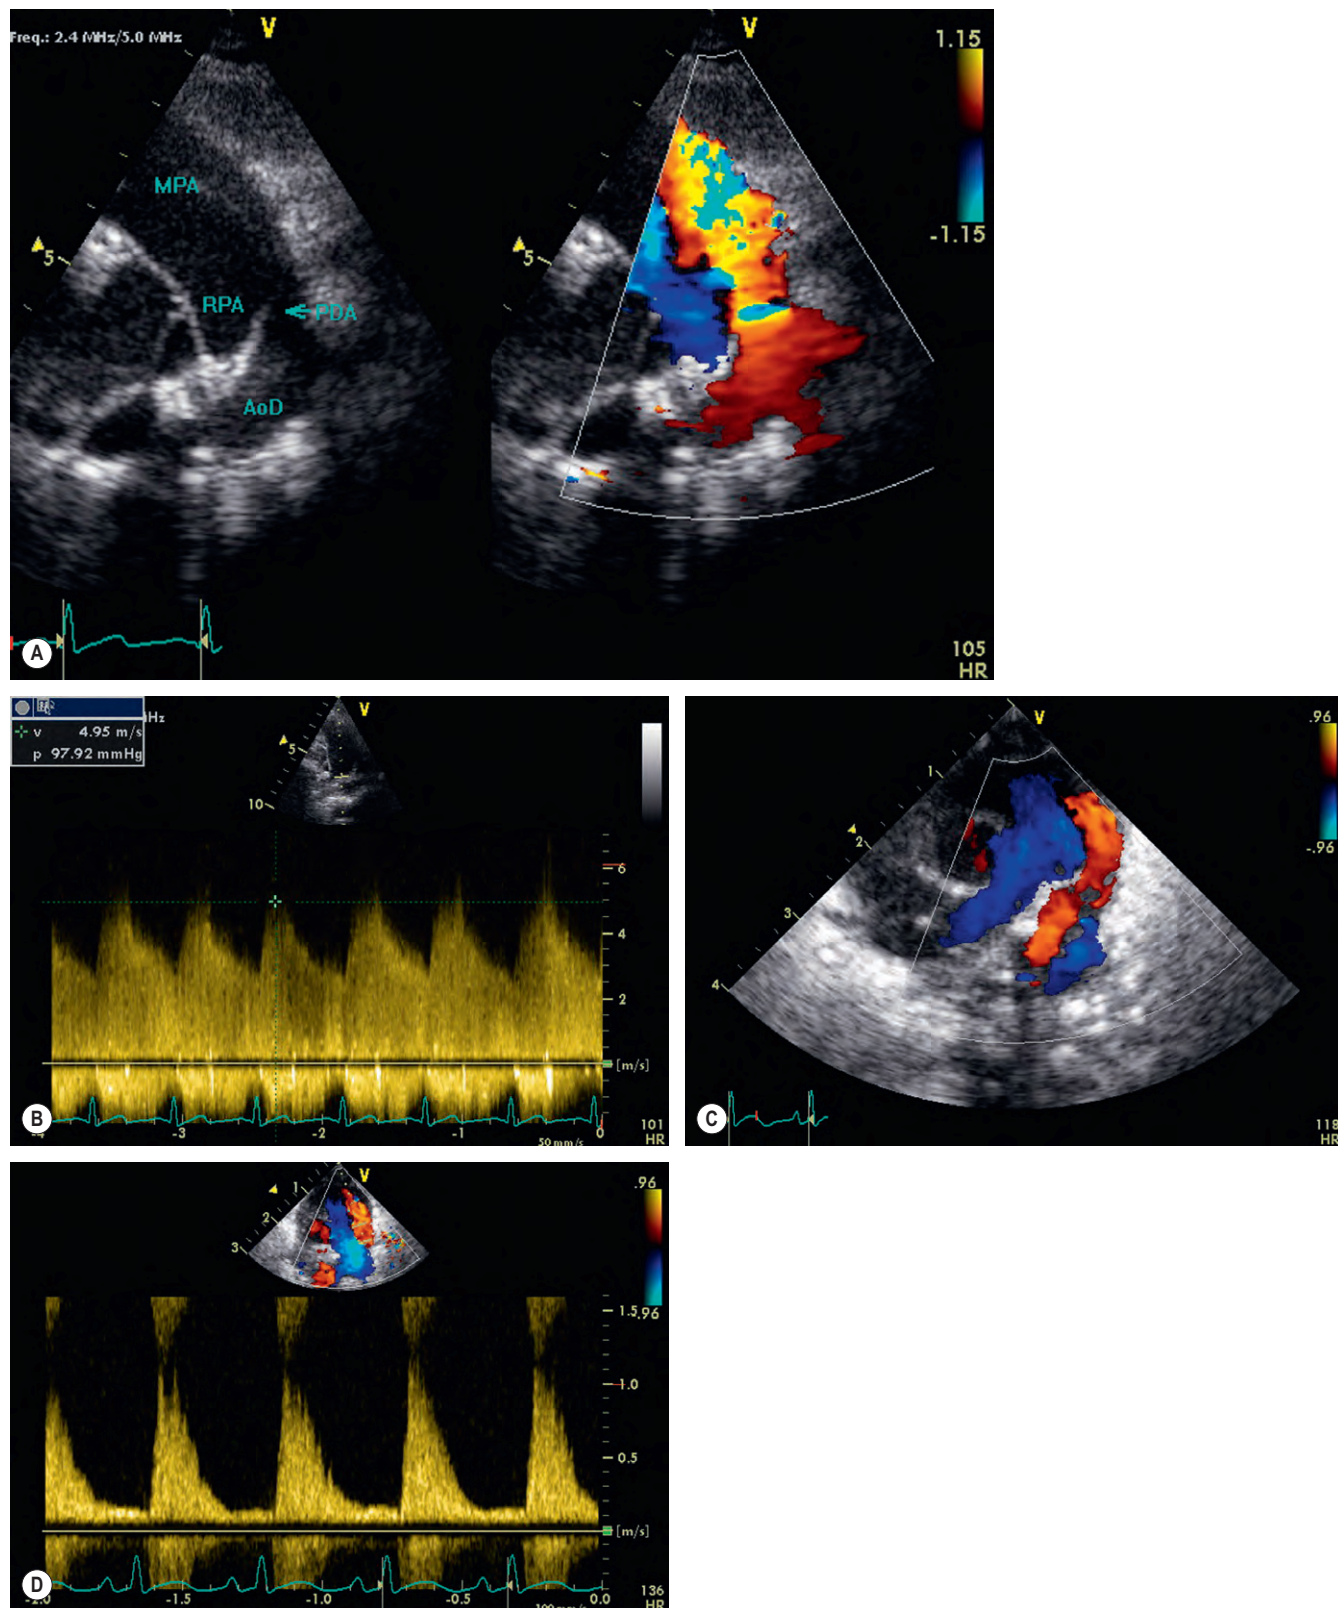

Fig. 28.18 (A) High parasternal short-axis view showing the arterial duct (patent ductus arteriosus: PDA) and the relationship with the main pulmonary artery (MPA) and descending aorta (AoD). Adjacent colour flow mapping image shows turbulent flow through a modest-sized PDA. (B) Spectral Doppler trace from the same patient shows high-velocity left-to-right flow (closing pattern). (C) Similar view to (A), with colour flow mapping showing laminar left-to-right flow through the PDA. (D) Spectral Doppler trace from same patient as in (C) with low-velocity left-to-right flow through the PDA (pulsatile pattern).

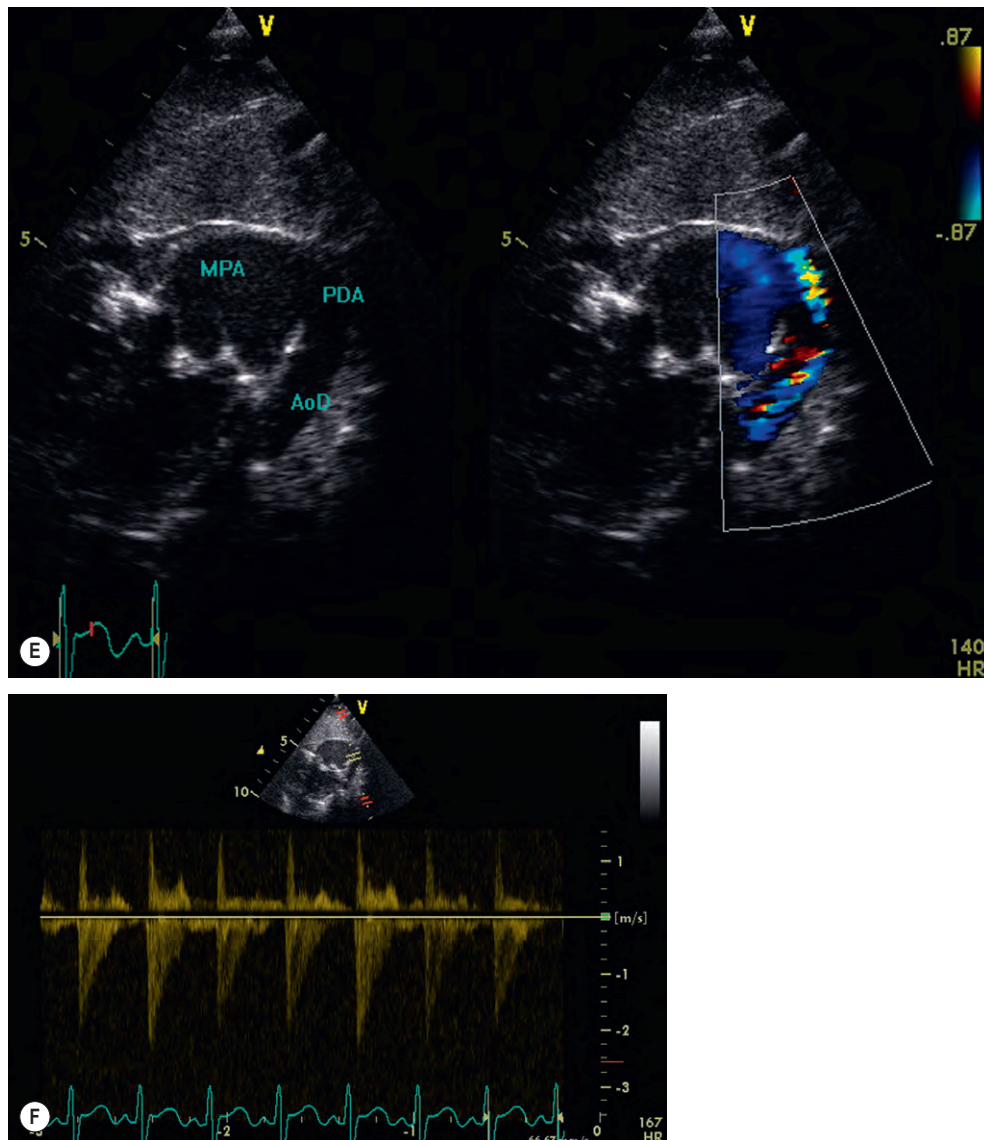

Fig. 28.18, cont'd (E) Similar view to (A) with a large PDA and right-to-left flow seen on colour flow mapping suggestive of pulmonary hypertension. (F) Spectral Doppler trace from same patient as in (E) confirming right-to-left flow associated with hypertension and, in this case, aortic coarctation.

Many thousands of babies have been enrolled in large numbers of trials to evaluate the benefit of prophylactic treatment of persistent DA. The largest of these (TIPP study; [Schmidt et al. 2001](#)) compared the effects of three daily doses of indometacin (100 µg/kg) with placebo in 1200 babies (birthweight <1000 g) given from day 1 of life. Their conclusions were that early prophylactic indometacin was associated with:

- significant reduction in PDA in the treated group (reduced need for further indometacin/surgery)
- significant reduction in intraventricular haemorrhage in the treated group
- no difference in mortality or long-term neurological outcome
- no difference in the incidence of necrotising enterocolitis or CLD.

The lack of clear benefit in neurodevelopmental outcome when indometacin is given prophylactically does not support the prophylactic use of non-steroidal anti-inflammatory drugs. Furthermore,

there is little convincing evidence to suggest improved short-term morbidity when indometacin is used prophylactically compared with its early administration once a PDA has started to cause symptoms. Use of another prostaglandin synthetase inhibitor, ibuprofen, within 3 hours of birth has been reported to reduce short-term morbidity and length of hospital stay ([Fowlie and Davis 2008](#)).

Clinical features and diagnosis

The picture of a baby with respiratory distress syndrome who is failing to improve or starts to deteriorate between 5 and 10 days of age, and who has some or all of bounding pulses, an active precordium and a continuous murmur in the pulmonary area, is easy to recognise. Progressive cardiomegaly and worsening lung shadowing on X-ray may be seen. Less gross physical signs in the clinical context may still allow a diagnosis to be made, even in the absence of a murmur. PDA can cause symptoms well before 5 days of age, particularly in infants who have received exogenous surfactant

(Couser et al. 1996); indeed, PDA may be important in the pathogenesis of pulmonary haemorrhage occurring after surfactant administration (Raju and Langenberg 1993). Apnoea in a non-ventilated baby is sometimes a manifestation of PDA and necrotising enterocolitis may be secondary to a widely patent duct. Echocardiography is more sensitive and specific than clinical signs (Evans and Archer 1990) and provides further information about the haemodynamic significance of the PDA. Echocardiographic evaluation includes visualisation of the ductus itself and Doppler evaluation of the pulmonary artery, the ductus and the descending aorta (Fig. 28.18). Additional features include volume loading of the left heart (unless there is a significant atrial communication which will unload the left heart and mask this finding). A continuous murmur in a preterm infant is far more likely to be due to PDA than to any structural lesion, but, if doubt exists, echocardiography must be performed. The little-understood systemic-to-pulmonary collateral arteries detected in preterm infants appear to be a transitory finding (Acherman et al. 2000) in most cases but cause a continuous murmur and can confuse in the diagnosis of PDA. The contribution of these vessels to CLD and the indications for intervention are unclear.

Treatment of PDA

As indicated above, this area remains very controversial (Benitz 2010). Medical and surgical interventions are used for closure of the DA in symptomatic premature infants but objective evidence on long-term outcomes to support such practice is very difficult to demonstrate. In the past, the DA was shown to close spontaneously in time in nearly all preterm infants without specific therapy (Hallidie-Smith 1972; Clarkson and Orgill 1974) but was associated with significant morbidity. By the mid-1970s surgical ligation was being performed on smaller infants and indometacin became available, which resulted in aggressive management of babies with a symptomatic PDA on the assumption that morbidity would be reduced. As a consequence of this, the natural history of the DA in extremely low-birthweight premature infants remains relatively unknown as these babies are almost invariably treated in current neonatal practice. However, the fact that some preterm infants with PDA will develop congestive heart failure, respiratory failure with pulmonary oedema and signs of other organ ischaemia is universally accepted. Some will improve rapidly after interventions to achieve ductal closure, suggesting that an active approach to the management of symptomatic PDA is likely to continue in most neonatal units.

First-line treatment involves optimising oxygen delivery by treating anaemia and achieving adequate arterial oxygen tension, as well as employing fluid restriction and diuretics. Loop diuretics such as furosemide are the most commonly used, although there are theoretical reasons as well as modest clinical evidence to suggest that furosemide may promote ductal patency by its effect on renal prostaglandin synthesis (Green et al. 1983). However, a short trial of fluid restriction and diuretic treatment is sometimes associated with clinical improvement. If there is no improvement, ductal closure is almost invariably recommended, either pharmacologically or by surgery.

Drug treatment is usually tried first unless a specific contraindication exists. Contraindications include:

- documented gastrointestinal tract or renal anomaly
- suspected CHD
- suspected or active necrotising endocarditis
- active bleeding or platelet count $<50\,000/\text{mm}^3$
- urine output $<0.6\text{ ml/kg/h}$ or raised creatinine
- active infection (Narayanis et al. 2000).

Indometacin is the most widely used drug. In a multicentre trial of babies under 1750 g birthweight, 21% developed sPDA and indometacin closed the ductus within 48 hours of administration in 79% of the 135 infants who received it. Spontaneous closure occurred in only 28% of controls in the same timescale. One-third of responders relapsed but many of these did not require further intervention. Many of those who did have further intervention responded to additional indometacin administration. Overall, indometacin had a 70% success rate, which was not influenced by the application of prior fluid restriction and diuretic therapy (Gersony et al. 1983). Many other studies have demonstrated similar results. Gestation under 28 weeks and postnatal age beyond 2 weeks are associated with lower success rates, as is antenatal indometacin exposure (Norton et al. 1993). Indometacin is usually given intravenously in a dose of 0.2 mg/kg on three occasions, with 8–12 hours between each dose. If a response is seen initially, but with later relapse, it is reasonable to give a further course. Some advocate an escalating stepwise dose schedule.

As well as constricting the DA, indometacin causes renal vasoconstriction, resulting in oliguria, fluid retention, hyponatraemia and elevation of blood urea and creatinine concentrations. These effects are transitory and rarely serious if fluid restriction is applied during treatment. The effect on gastrointestinal blood flow may be the explanation for gastrointestinal haemorrhage and perforation, which are seen in less than 10% of recipients of indometacin. Cranial Doppler ultrasound demonstrates significant falls in cerebral blood flow velocity after rapid intravenous administration of indometacin (Evans et al. 1987) but not if the drug is given more slowly over 30 minutes. However, near-infrared spectroscopy shows marked and prolonged reduction in cerebral blood flow and volume, cerebral oxygen delivery and cerebral vascular responsiveness, regardless of the speed of administration of the drug (Edwards et al. 1990). The evidence that indometacin reduces cerebral blood flow is countered by clear evidence that it reduces the incidence of intraventricular haemorrhage (Wells and Ment 1995) and that PDA has adverse effects on cerebral haemodynamics (Shortland et al. 1990; Evans and Kluckow 1996). A 5-day course of indometacin (Hammerman and Kaplan 1990) has been shown to reduce the relapse rate, and a 6-day lower dose (0.1 mg/kg/day) course (Rennie and Cook 1991) is associated with lower relapse rates and less biochemical disturbance.

It is not known what cerebral haemodynamic disturbances accompany these longer courses of indometacin. Ductal Doppler waveforms referred to above (Su et al. 1997) have been used to reduce the number of doses of indometacin used if evolution in the pattern from growing or pulsatile to closing (high-velocity left-to-right, Fig. 28.18) is documented before a standard course of the drug is completed. Side-effects would also appear to be reduced by this approach (Su et al. 1999). Ibuprofen has been shown to be as effective at closing the ductus in extremely preterm infants but without disturbances of cerebral haemodynamics, as demonstrated by near-infrared spectroscopy (Patel et al. 1995, 2000) and also to cause less disturbance of renal function (Van Overmeire et al. 2000) than three doses of indometacin 0.2 mg/kg administered 12 hours apart. There are current problems with availability of a suitable intravenous preparation of ibuprofen, and intravenous indometacin, in many countries.

Surgery

Surgical occlusion of sPDA is indicated if a clear contraindication to indometacin administration exists, or if the drug is ineffective. Relapse after a second short course of indometacin or after a single 6-day course is also an indication for surgery. Surgery can be

Fig. 28.19 Schematic representation of the potential sites of anomalous pulmonary venous connection (see Fig. 28.2).

performed in the neonatal intensive care nursery with acceptable morbidity and low short-term mortality, although this group of patients has been reported to have a 10% mortality before discharge from hospital (Robie et al. 1996).

Chronic lung disease

The pathogenesis of CLD is complex (Ch. 27, part 3) and a contribution from a PDA seems likely, although early intervention to close a PDA has not been shown to reduce its incidence. Other left-to-right shunt lesions may contribute to or be masked by chronic respiratory problems. Sustained or recurrent hypoxaemia secondary to CLD results in elevation of PVR with consequent pulmonary hypertension and right-heart enlargement. Steroid administration for treatment of CLD may cause cardiac hypertrophy with or without systemic hypertension, which may result in dynamic left ventricular outflow obstruction (Evans 1994). These changes are rarely of clinical significance and resolve with cessation of steroid therapy. Electrocardiographic and echocardiographic assessment of infants with CLD is appropriate to judge RVH and to get non-invasive (Doppler) evaluation of right heart pressures. Diuretics are of value if pulmonary oedema occurs and are also indicated if systemic venous engorgement occurs secondary to elevated right-heart pressures. There are anecdotal reports of successful use of pulmonary vasodilator therapy in the treatment of elevated right-heart pressures in association with CLD but consistent data are lacking. Reduced ventricular function or atrial dysrhythmias are late and very serious findings.

Endocarditis

Infective and non-infective thrombotic endocarditis occurs in critically ill newborn infants with structurally normal hearts, particularly the preterm (Opie et al. 1999). Clinical features are non-specific, but recurrent or relapsing bacteraemia or the presence of multiple infected sites should raise suspicion of infective

endocarditis. Splenomegaly and microscopic haematuria are often present, but these have many other possible causes. Indwelling arterial or central venous cannulae are major risk factors for thromboembolic phenomena and infection. Echocardiography is helpful in diagnosis by recognition of intracardiac vegetations (Fig. 28.16B). Treatment involves removal of infected or potentially infected lines and culture-guided antibiotic therapy, which may need to be prolonged.

Arrhythmias

The same types of arrhythmia may occur in preterm infants as in term babies and are dealt with in pages 661–663. In general, tachyarrhythmias are less well tolerated in preterm infants than in term babies and require prompt intervention to restore sinus rhythm using pharmacological or electrical cardioversion. CHB is difficult to manage in premature babies because of the technical difficulties associated with trying to implant pacemakers into very small infants.

Structural heart disease in the preterm infant

Structural heart disease may occur in the preterm infant and is becoming more prevalent with the rapid improvements in neonatal care of preterm infants. Frequently, the respiratory problems associated with prematurity will mask the cardiac pathology. Diagnosis may also be delayed because of more pressing clinical concerns and because of the tendency towards delayed ductal closure in premature newborns. If the baby is being considered for ductal intervention because of sPDA, then a full echocardiographic examination is indicated. The identification of structural CHD in preterm infants will invariably complicate their management whilst on the neonatal unit. Long periods of prostaglandin administration whilst waiting for weight gain sufficient to consider surgical intervention bring their own hazards in duct-dependent lesions. Lesions with left-to-right shunts will exacerbate acute respiratory problems as well as increasing the risk of CLD and early-onset PVD. Palliative surgical interventions such as pulmonary artery banding for VSDs may improve outcome but such surgery is associated with significant morbidity in low-birthweight infants. Overall prognosis for the same lesion is significantly worse when occurring in premature versus term infants (Andrews et al. 2006).

Structural heart disease in the newborn

Heart disease in the newborn presents in one of four main ways:

1. cyanosis
2. collapse
3. heart failure
4. murmurs.

Cyanosis

The causes of cyanosis are listed in Table 28.13. In practice, it is often possible to distinguish respiratory and cardiac causes on clinical grounds; Table 28.14 gives details of helpful discriminating features. If cardiac disease is thought definite or likely, an approach to management is given in Table 28.15. Clinical features, ECG and CXR often allow an approximate cardiac diagnosis to be made. Echocardiography allows very precise diagnosis in the vast majority of cases. It is more important to stabilise an infant before transfer

Table 28.13 Conditions presenting with neonatal cyanosis

CATEGORY	DETAIL	COMMENT
Respiratory	Any respiratory disease	
Cardiac	Inadequate pulmonary blood flow with right-to-left shunt Pulmonary atresia with intact ventricular septum Pulmonary atresia, ventricular septal defect Tricuspid atresia Tetralogy of Fallot Ebstein's anomaly Adverse mixing Transposition of the great arteries Common mixing TAPVC DIV DOV Truncus arteriosus	20% cyanosed as newborn Especially if obstructed Degree of cyanosis reflects severity of PS Heart failure common Heart failure common
Persistent pulmonary hypertension	See Ch. 27, Part 2	
Haematological	Methaemoglobinaemia	Grey/black rather than blue, arterial oxygen tension normal
TAPVC, total anomalous pulmonary venous connection; DIV, double-inlet ventricle; PS, pulmonary stenosis; DOV, double-outlet ventricle.		

Table 28.14 Clinical features helpful in distinguishing respiratory from cardiac cyanosis. Note all categories have overlap between respiratory and cardiac causes

	RESPIRATORY CYANOSIS	CARDIAC CYANOSIS
History	Prematurity, meconium liquor/below cords, risk of infection	Family history of congenital heart disease
Respiration	Marked respiratory distress	Little or no respiratory distress unless shocked or metabolic acidosis
Cardiovascular examination	Normal	May have clear signs
Response to oxygen	Cyanosis likely to improve	Cyanosis unlikely to improve dramatically
Chest X-ray	Obvious respiratory pathology Normal CTR (cardio thoracic ratio)	No respiratory pathology, abnormal heart shadow or lung vasculature may be seen
Electrocardiogram	Normal	May be normal, may be helpful
Blood gases	Hypercapnia	Hypo- or normocapnia

to a cardiac centre than to get a precise diagnosis by ultrasound. Differentiating cardiac disease from PPHN may require echocardiography and the two may coexist (Table 28.16). Specific cyanotic conditions are discussed below. As previously discussed, cardiac cyanosis occurs as a result of obstruction to pulmonary blood flow with a right-to-left shunt, adverse streaming of blood on the heart or in association with common mixing of blood at atrial, ventricular or great artery level.

Pulmonary atresia

In all forms of this condition, the pulmonary valve and sometimes the subvalvar ventricular outflow tract are completely blocked, so there can be no forward flow from the right ventricle into the pulmonary artery. Valve morphology varies and may consist of two or three thin cusps which are fused, or the cusps may be extremely thick, dysplastic and immobile. Whatever cusp morphology exists,

the valve ring itself is usually small in addition. Hearts with pulmonary atresia can be further subdivided as follows:

- with intact ventricular septum – pulmonary circulation always duct-dependent (includes neonates with critical pulmonary valve stenosis)
- with VSD – pulmonary circulation duct-dependent or pulmonary blood supply from major aortopulmonary communicating arteries (MAPCAs)
- as part of complex cyanotic heart disease, for example as in univentricular heart with pulmonary atresia.

Table 28.15 Management of newborn infant with suspected cyanotic congenital heart disease

1. General measures should be directed to reducing stress:
Maintain temperature
Avoid hypoglycaemia
If well, proceed to 3
2. If unwell:
Arterial blood gas
 - Treat respiratory failure; ventilate if necessary
 - Hypoxaemia alone not reason to ventilate
 - Treat metabolic acidosis
 - Consider hyperoxia test
 Consider prostaglandin (use if in doubt)
3. Chest X-ray:
Diagnostic clues may be present
Aid in management
 - Oligoemia: start prostaglandin
 - Plethora: start prostaglandin if very hypoxaemic or metabolic acidosis
4. Electrocardiogram: may point to specific diagnosis
5. Review:
Drugs
 - Prostaglandin as above
 - Bicarbonate
 - Diuretic if heart failure/pulmonary congestion
 Antibiotics (infection should always be considered as differential diagnosis)
6. Echocardiography:
If infant requires transfer, stabilise first
Usually gives precise cardiac diagnosis

Pulmonary atresia with intact ventricular septum

This condition always presents with severe cyanosis in the early newborn period, thereby making up 2.5% of symptomatic newborns with CHD but <1% of all lesions. The main pulmonary artery and its branches are usually confluent and of reasonable size, whereas the right ventricle and tricuspid valve are underdeveloped, sometimes severely so with severe RVH. The tricuspid valve is frequently malformed by tethering of its septal leaflet or displacement toward the apex (Ebstein's malformation), resulting in significant tricuspid regurgitation. Anomalies of the coronary supply to the right ventricle are common and may affect outcome. There is right-to-left shunting at atrial level. If the foramen ovale is or becomes restrictive, marked right atrial enlargement and systemic venous engorgement occur. Pulmonary blood flow is duct-dependent, and extreme cyanosis with metabolic acidosis develops as duct closure progresses. Resuscitation includes prostaglandin and, sometimes, balloon atrial septostomy. Interventional catheterisation can be used as initial treatment (Weber 2002) to perforate and dilate the pulmonary valve if appropriate and/or to stent the arterial duct, but many centres use a surgical approach, the exact sequence depending on echocardiographic assessment of the RV cavity and tricuspid valve sizes. Evaluation of coronary abnormalities using echocardiography, and angiography if needed, may influence management. Primary opening up of the RV outflow tract (RVOT) is desirable if at all possible; systemic-to-pulmonary arterial anastomosis (modified Blalock–Taussig shunt) may be required in addition. These approaches give survival to school age in the region of 80%. If RV hypoplasia is so severe that, even in the neonatal period, it is clear that a biventricular circulation cannot ultimately be established, a systemic-to-pulmonary shunt is performed in the newborn period with the eventual aim of achieving a Fontan-type circulation. In this type of circulation, systemic veins are connected to the pulmonary

Table 28.16 Features helpful in differentiating persistent pulmonary hypertension of the newborn (PPHN) from cyanotic heart disease

	PPHN	CYANOTIC HEART DISEASE
History	Maternal prostaglandin synthetase inhibitor therapy	May have positive family history
Delivery	Fetal distress, birth asphyxia	Uneventful
Examination	Respiratory and/or neurological signs	May have clear cardiac signs
Chest X-ray	May have respiratory pathology	May have diagnostic cardiac/vascular features Often non-specific
Electrocardiogram	May have RAH, ischaemic changes	May have clear abnormality
Hyperoxia test	Variable response, may pass, not if severe fluctuating arterial oxygen tensions seen	Usually poor response
Upper/lower limb saturations	Lower limb often lower (if DA patent)	Occasionally marked discrepancy
Echocardiography	Usually can exclude heart abnormality but can be difficult	Usually diagnostic but cardiac defects may be overlooked
Note: There can be marked overlap and both can coexist. RAH, right atrial hypertrophy; DA, ductus arteriosus.		

arteries without passage of systemic venous blood through a ventricle.

Critical pulmonary valve stenosis has many features in common with this situation except that there is forward flow through the pulmonary valve and the right heart is rarely markedly hypoplastic. Infants with critical pulmonary stenosis should be treated with primary balloon dilatation, usually with a good result, even if further intervention in the form of repeat pulmonary balloon dilatation is needed in later infancy.

Pulmonary atresia with VSD

In contrast to PA with intact ventricular septum, where the anatomical problem is associated with underdevelopment of the right ventricle and associated structures, if there is a VSD present, it is the pulmonary arterial supply that is the major determinant of outcome. The spectrum of disease varies from mild tetralogy of Fallot with confluent and adequate-sized pulmonary arteries to those infants who have non-confluent and severely underdeveloped pulmonary arteries. Pulmonary blood supply may come entirely via the DA (when the pulmonary arteries are confluent) or it may come partly or entirely from other vessels arising from the aorta (MAPCAs) or head and neck branches. The degree of cyanosis and other physical signs will depend on the amount of flow into the pulmonary circulation. If MAPCAs are large or plentiful, cyanosis is milder, continuous murmurs are heard all over the chest and heart failure may develop. This group of conditions has a significant association with extracardiac malformations, syndromes and chromosomal abnormalities. 22q11 deletion must be remembered as this syndrome has important implications for management, with increased risk of symptomatic hypocalcaemia, immunodeficiency and, if transfused non-irradiated cellular blood products, of graft-versus-host disease. If pulmonary blood flow is duct-dependent, prostaglandin will be needed and early palliative surgery is indicated. If sources of lung blood supply are complex, detailed evaluation with angiography or alternative imaging is required in early infancy in order to assess surgical options. Long-term outcome is variable, but is dependent on the pulmonary arterial supply. With confluent central pulmonary arteries a survival of 80% or more is likely, even if multiple surgical procedures are required. When the pulmonary arterial supply is derived from MAPCAs then outcome is much less favourable with significant morbidity.

Pulmonary atresia as part of a complex lesion

These infants usually have duct-dependent pulmonary blood flow and their condition will be improved by prostaglandin. Obstruction to the systemic arterial outflow of the heart exceedingly rarely coexists, just as complex lesions with systemic outflow obstruction very rarely have significant pulmonary outflow obstruction. However, almost any other cardiac structural abnormality can coexist. Thus, clinical features in addition to cyanosis vary, as do appropriate treatments. In the newborn period, surgical interventions, when appropriate, are likely to be only palliative. Extracardiac abnormalities are common and long-term outcome is often poor for both cardiac and non-cardiac reasons, particularly in those with right atrial isomerism, in whom asplenia with an increased risk of serious bacterial infection is usually present amongst other non-cardiac complications.

Tetralogy of Fallot

This constitutes 10% of all cases of structural heart disease, but only 20% of patients with tetralogy of Fallot are cyanotic in the newborn

period. RV outflow obstruction is always subvalvar (infundibular) but may be valvar and supravalar in addition. RV outflow obstruction and a large VSD cause RVH. The VSD is subaortic with the aorta arising in part from the right ventricle (overriding aorta); it is rarely restrictive and additional significant VSDs are occasionally found. PFO or ASD commonly coexists; rarely, the pulmonary valve is absent (see below) and tetralogy of Fallot can coexist with complete AVSD. Patients presenting with cyanosis as newborns may have pulmonary atresia or a very narrow but patent RVOT. Those with pulmonary atresia will be duct-dependent. Tetralogy of Fallot without cyanosis in the newborn period is associated with a pulmonary outflow murmur, although it is frequently mistaken for a VSD murmur. Cyanosis is progressive during the first year of life as subvalvar muscular RVOT obstruction increases. Hypercyanotic spells due to infundibular constriction are rare in the newborn period but are an indication for palliative or corrective surgery. Emergency management of spells includes:

- facial oxygen (although whilst the spell occurs it is unlikely to improve oxygenation)
- morphine (50–100 µg/kg s.c., i.m. or i.v.)
- phenylephrine 20 µg/kg i.v.
- propranolol 20 µg/kg slowly i.v., may be repeated once
- heavy sedation/anaesthesia and assisted ventilation
- administration of intravenous fluids to increase circulating volume.

It is rare to need to progress beyond morphine in this protocol. Intravenous drugs should only be used in a setting where ventilation and full cardiopulmonary resuscitation can be given. Spells are usually mild initially and get progressively more frequent, severe and prolonged. Oral propranolol (1–2 mg/kg) three times daily usually prevents recurrent spells in the short and medium term whilst surgical strategies are decided.

Tetralogy of Fallot with absent pulmonary valve

This rare variant of tetralogy (<5% of cases) has small dysplastic pulmonary valve leaflets resulting in marked pulmonary regurgitation and dilatation, often massive, of the pulmonary arteries. The large pulmonary arteries compress the bronchi so that bronchomalacia develops in utero. Presentation in the newborn period is often with airway obstruction causing pulmonary collapse or over-inflation. Cyanosis is not usually marked in early infancy. Impressive systolic and diastolic murmurs from the RVOT with a single S2 in the context of airway obstruction strongly suggest the diagnosis. The dilated pulmonary arteries are seen on CXR; RVH is apparent on ECG. Severe bronchomalacia and pulmonary hypoplasia often cause death even if technically satisfactory cardiac surgical repair is achieved. Surgical mortality in those presenting early with severe pulmonary problems may be as high as 50%.

Tricuspid atresia

Tricuspid atresia represents about 2% of structural heart lesions. Associated abnormalities include VSD and TGA. Those without TGA will frequently have pulmonary stenosis whereas those with TGA may have coarctation. Blood leaves the right atrium via the foramen ovale or an ASD. If the VSD is large or there is TGA, pulmonary blood flow will be high and cyanosis mild, with the possibility of heart failure developing. A restrictive VSD and/or severe pulmonary stenosis will produce duct-dependent pulmonary circulation. A number of patients will be haemodynamically well balanced and will not require intervention until the second half of infancy. Coarctation with TGA in this setting may result in collapse from

Table 28.17 Cardiac conditions which may present with collapse

Arrhythmias – primary or secondary
Duct-dependent circulation
Transposition – ASD, VSD, PDA Pulmonary Pulmonary atresia with intact ventricular septum Tricuspid atresia – with restrictive VSD
Systemic
Hypoplastic left heart Aortic atresia Critical aortic stenosis Interrupted arch Coarctation
Duct-dependent cardiac conditions often present with other signs (cyanosis or respiratory distress) before collapse occurs. ASD, atrial septal defect; VSD, ventricular septal defect; PDA, patent ductus arteriosus.

duct-dependent systemic circulation. Clinical features are given in [Table 28.17](#). The long-term goal is a Fontan circulation, and either systemic-to-pulmonary anastomosis or pulmonary artery banding is usually required in infancy as palliation and, if the VSD is large, to ensure undamaged pulmonary vasculature. Tricuspid atresia is the lesion with the best univentricular long-term outlook with a Fontan circulation, with an operative mortality in childhood of under 10% and a 75% 15-year good-quality survival thereafter.

Transposition

TGA represents approximately 5% of cases of structural CHD; it is rarely found in preterm infants and is rarely associated with extra-cardiac abnormalities or syndromes. It is commoner in males by a factor of 3. Associated cardiac conditions include ASD, VSD, PDA, valvar and subvalvar pulmonary stenosis, and aortic coarctation. Clinical signs will be determined by the associated abnormalities; in principle, the fewer and smaller the shunt lesions, the less mixing of blood occurs and the more severe the cyanosis will be. Presentation is occasionally delayed beyond the first week of life but in those with no shunts is usually within a few hours of birth, occasionally with severe acute cyanosis and shock. Marked pulmonary outflow obstruction will result in worse cyanosis as well as a loud murmur with pulmonary oligoemia on CXR, whereas in the absence of pulmonary stenosis, pulmonary plethora is the more usual finding. Cases with large shunt lesions will not require immediate intervention to improve oxygenation; those without large shunt lesions will usually improve oxygenation enough to avoid metabolic acidosis if the DA is opened with prostaglandin. In some cases, enlargement of the foramen ovale by balloon septostomy will be necessary to obtain adequate entry of well-saturated blood into the right ventricle, even if the DA has been reopened. Balloon septostomy can be done in the neonatal nursery under ultrasound control.

Coexistent coarctation must be repaired and the arterial switch operation is performed in the newborn period unless there is marked fixed pulmonary outflow obstruction, in which case the switch operation is not appropriate and a systemic-to-pulmonary anastomosis will be needed, with definitive surgery being deferred for some years. In TGA with intact ventricular septum the arterial

switch operation is ideally performed before left ventricular muscle has involuted in response to serving the lower resistance pulmonary circulation. The timescale in which this happens is unclear, but surgery under 3 weeks of age is within a safe margin but has been successfully undertaken in babies of up to 3 months. If there is a large VSD that does not reduce in size spontaneously, the timescale is not as pressing but there is no particular advantage in delaying surgery beyond 2 months. A baby with TGA who presents beyond the early newborn period needs careful assessment to be sure that the left ventricular pressure remains high.

Coronary artery anatomy is clearly important to the surgeon and can often be delineated by echocardiography. Neonatal arterial switch operative mortality is <5% for simple TGA. Repair of transposition by intra-atrial repair (Mustard or Senning operations) is uncommonly performed now because of long-term problems with arrhythmias and RV failure.

Total anomalous pulmonary venous connection

Entry of pulmonary veins into systemic venous pathways can be at one site or several (mixed TAPVC). Most commonly, the pulmonary veins all enter a confluence behind, but separate from, the left atrium. The confluence then drains directly or indirectly into the right atrium. Drainage can be classified as in [Figure 28.19](#). Obstruction to the pulmonary venous return can occur at a number of sites, including the pulmonary vein orifices, on entry of the confluence to the systemic veins, in the ascending vein as it courses upwards to join the innominate vein in supracardiac TAPVC, on passage through the diaphragm and on passage through the liver after the ductus venosus closes in infradiaphragmatic TAPVC. Obstruction to the pulmonary veins will cause worse cyanosis, marked respiratory distress and less cardiomegaly than unobstructed TAPVC and may prove difficult to distinguish from PPHN even with echocardiography. There is always a PFO and often an ASD (providing mixing at atrial level), with entry of blood to the left heart only through these means; thus, varying degrees of left ventricular underdevelopment are common. Coarctation and even severe hypoplasia of the left heart are very occasionally present.

TAPVC forms part of the complex abnormalities associated with left and right isomerism. In general, the more severe the pulmonary venous obstruction, the earlier the infant is symptomatic. Infradiaphragmatic TAPVC to the portal vein is associated with marked cyanosis and respiratory distress, which gets dramatically worse when the ductus venosus shuts. As they sometimes present early and very blue, infants with obstructed TAPVC often receive prostaglandin, sometimes with benefit to their general state. This improvement is presumably due either to opening of the DA and decompression of the right heart or to opening of the ductus venosus and ameliorating pulmonary venous hypertension in TAPVC to the portal vein. Infants with completely unobstructed TAPVC are sometimes not recognised until after the newborn period when recurrent respiratory tract infections and failure to thrive occur. Management is by corrective surgery, with mortality below 10% and, usually, an excellent long-term outlook. Recurrent pulmonary vein stenosis may occur after surgical repair and is more common in neonates presenting with severe disease early in the neonatal period.

Complex structural cyanotic congenital heart disease

These conditions often include more than one of the above abnormalities as well as shunt lesions and obstruction to either systemic or pulmonary arterial outflow tracts. Important pulmonary and

systemic outflow obstruction very rarely coexists. Mixing of blood may occur at atrial, ventricular or at great artery level (or at more than one site). Most complex cyanotic lesions have a univentricular arrangement or have significant imbalance between the sizes of the two ventricles. Association with extracardiac abnormalities is common and, in addition to specific system abnormalities, the possibility of atrial isomerism must be considered. Atrial isomerism (sometimes termed situs ambiguus or heterotaxy) exists when abdominal, bronchial and atrial anatomy is neither the usual arrangement (situs solitus) nor a mirror image of the usual arrangement (situs inversus). The usual arrangement of viscera involves spleen and stomach being on the left-hand side and liver on the right, a morphologically left lung being on the left and a morphologically right lung (three-lobed) being on the right with a morphologically left atrium being to the left of the morphologically right atrium. Situs inversus is a mirror image of this arrangement and atrial isomerism exists when both lungs are of the same morphology (right or left) and both atria are of the same morphology (right or left). When this situation exists, the liver tends to be midline, stomach position is variable and there is either asplenia (in right isomerism) or polysplenia (in left isomerism). Very rarely the situation is less clear-cut and there are some features of right and left isomerism in the same patient.

Generally, right isomerism is associated with severe cyanotic CHD comprising TAPVC, complete AVSD and pulmonary atresia or severe pulmonary stenosis with or without transposition. The cardiac abnormalities associated with left isomerism are more variable in range and severity, but abnormalities of the systemic and pulmonary venous drainage are frequent. Cardiac lesions with left isomerism are not always cyanotic, are more commonly associated with obstruction to the systemic outflow and will invariably have an arrhythmia which varies from 'sinus' with an abnormal atrial pacemaker to CHB associated with a very poor prognosis. Clues to the presence of this type of complex abnormality include a midline liver and dextrocardia. Immediate management principles include deciding whether prostaglandin is indicated: the same criteria apply in these circumstances as in any other.

Common arterial trunk or truncus arteriosus

This malformation constitutes >1% of congenital heart lesions; it is associated with 22q11 deletion in 30% of cases. A single outlet arises from the heart, giving rise to coronary and pulmonary arteries as well as to the aortic arch, which is right-sided in 30% of cases and interrupted in 5–10%, in which case the association with 22q11 deletion is very high. This is an example of cyanosis caused by common mixing predominantly at great artery level. The VSD is usually large and the common arterial trunk overrides it; the truncal valve is abnormal and may be regurgitant or stenosed or a combination of both. Pulmonary arteries arise either laterally from the truncus, adjacent and posteriorly, or from a short main pulmonary artery. Absence of one pulmonary artery occasionally occurs.

Stenosis at the origin of a pulmonary artery if present is rarely severe; thus, high pulmonary blood flow and pressure result in early-onset PVD if the baby survives infancy without surgery. Clinical presentation is cyanosis, tachypnoea or a cardiac murmur. Heart failure occurs later in the newborn period as PVR falls. Severity of cyanosis varies but is usually only mild; other features are listed in Table 28.21. The severity and haemodynamic effect of the truncal valve abnormality influence the signs detected, as does the PVR. Definitive diagnosis is by ultrasound, and, providing both pulmonary arteries can be demonstrated, further cardiac investigation is not normally required before surgery. Corrective surgery is indicated in early infancy to avoid irreversible progressive PVD.

Chromosome 22q11 deletion and immune status should be investigated preoperatively.

The long-term outlook is determined not only by the cardiac state but also by neurodevelopmental and immunological aspects of 22q11 deletion. Corrective surgery is undertaken in the neonatal period or in early infancy and involves closure of the VSD, detachment of the pulmonary arteries from the trunk and placement of a right ventricle to pulmonary artery conduit. If present, the interrupted aortic arch is also repaired. Surgical repair has a mortality of 10% or less but further surgery in the form of replacement of the RV to pulmonary artery conduit will be required in later childhood. In addition, many patients will need truncal valve surgery at some stage, although not usually at initial intervention. If truncal valve replacement is required as part of neonatal correction, surgical mortality increases significantly.

Ebstein's anomaly of the tricuspid valve

This abnormality is characterised by downward displacement of the tricuspid valve towards the apex of the right ventricle. It accounts for 0.5% of all congenital heart defects and, in most cases, it occurs in the setting of laevocardia with concordant AV and ventriculoarterial connections. Ebstein's anomaly has a variable clinical course depending on the degree of tricuspid valve abnormality. The abnormal tricuspid valve is almost always regurgitant and may be stenotic, both problems contributing to reduced forward flow through the right ventricle. When presenting in the newborn period, it is likely that the severity of tricuspid valve abnormality and associated lesions is significant. Neonates will usually present with severe congestive cardiac failure and cyanosis because of a combination of mixing at atrial level and inadequate pulmonary blood flow. The cardiac problems are often compounded by respiratory difficulties caused by pulmonary hypoplasia secondary to severe cardiomegaly. Survival is likely to be poor if symptoms are severe in the neonatal period largely because of limited available surgical options. Therefore, management tends to be conservative with the hope that, as PVR falls, there will be improved forward flow through the right ventricle and, with it, symptomatic improvement. A prostaglandin infusion to maintain ductal patency with simultaneous pulmonary vasodilator therapy may help until PVR has fallen sufficiently to facilitate antegrade flow across the pulmonary outflow. When there is associated pulmonary atresia, a neonatal systemic to pulmonary artery shunt might be appropriate but it should be remembered that these patients are likely to represent the worst end of the disease spectrum of this condition and will often have a poor medium to long-term outlook even if a neonatal shunt is successful. Occasionally, undiagnosed neonates may present with supraventricular arrhythmias because of the associated right atrial dilatation. Increasingly sophisticated repairs of the tricuspid valve in this condition are becoming more popular with improving results but are not appropriate until later in childhood (da Silva et al. 2007).

Congenitally corrected transposition of the great arteries

Congenitally corrected transposition is included in this section as it is frequently associated with additional intracardiac lesions and, in the neonatal period, most patients present with cyanosis because of associated pulmonary outflow tract obstruction. It is a very uncommon abnormality (<1% of structural heart lesions) and involves not only ventriculoarterial discordance (as in TGA) but also AV discordance. Thus, pulmonary venous blood passes from the left atrium through the tricuspid valve into the morphological right ventricle and then is ejected into the aorta. Desaturated systemic

venous blood passes through the right atrium and morphological left ventricle into the pulmonary artery. There may be dextrocardia and sometimes situs inversus. If there are no associated defects, infants are pink and the condition may not be suspected until long after the newborn period. VSDs occur in 75–80% of patients and will often cause heart failure in infancy unless important pulmonary stenosis coexists. Systemic AV valve regurgitation develops in about 30% of patients in later life and arrhythmias can develop at any age from fetal life onwards, including all degrees of AV block and SVT. Murmurs depend on associated lesions. The ECG may have heart block of any degree or a pre-excitation pattern. There are Q waves in V₁ and none in V₅₋₆.

CXR will be affected by associated lesions; it may show an abnormal heart position and often has a prominent left upper heart border due to the ascending aorta. Palliative surgery in the form of a systemic-to-pulmonary artery shunt is indicated in symptomatic infants with cyanosis. In infants with a VSD and no obstruction to pulmonary outflow, pulmonary artery banding is almost always the initial surgical intervention performed with further management dependent on the specific anatomical details in individual patients.

Collapse

Conditions that commonly present with collapse are listed in Table 28.17. Differentiating cardiac from non-cardiac causes is usually not difficult although conditions with duct-dependent circulation can, when the duct closes, mimic septicaemia and primary metabolic disorders. A cardiac cause should always be considered as part of the differential diagnosis in all cases of neonatal collapse. It is often necessary to start a prostaglandin infusion before a definitive cardiac diagnosis has been made. On the assumption that the cardiac collapse has occurred secondary to closure of the DA, it is necessary to start prostaglandin at high dosage to try and reopen the DA (Table 28.15). This increases the risk of apnoeic episodes but, usually, neonates who have collapsed will need intubation and ventilation and may require inotropic support as well.

Arrhythmias

These are discussed in a separate section. In the newborn period, arrhythmias that cause sudden unexpected collapse with no signs and a normal ECG between episodes are very rare.

Duct-dependent pulmonary circulation and transposition

These infants will normally be recognised as cyanosed and are discussed under that heading. Duct-dependent pulmonary circulation will result in extreme cyanosis and metabolic acidosis when ductal closure occurs, as will TGA if there is no mixing between systemic and pulmonary circulations via a VSD or an ASD.

Duct-dependent systemic circulation

These lesions are listed in Table 28.17, with clinical features being given in Table 28.18. They are all likely to have at least mild respiratory distress and some physical signs prior to collapse, but those features may have been unrecognised, especially if early discharge home occurred. Resuscitation must not be delayed awaiting echocardiography if the clinical picture is at all suggestive of duct-dependent systemic circulation.

Hypoplastic left-heart syndrome

This term is loosely used to describe a group of closely associated abnormalities whose common morphological feature is severe hypoplasia of the left-heart structures (of insufficient size to support the systemic circulation). It accounts for 2–3% of all CHD but a significantly higher proportion of antenatally detected and neonatal CHD. Extracardiac abnormalities are only occasionally encountered in liveborn infants with HLHS but subtle dysmorphism has been noted in up to 10% of cases (Wernovsky and Newburger 2003). Developmental abnormalities of the brain occur in up to 30% of

Table 28.18 Structural heart lesions presenting with respiratory distress or collapse in the early newborn period. All may have cyanosis if persistent pulmonary hypertension of the newborn or shocked; all have cardiomegaly with congested lung fields on chest X-ray

CONDITION	PULSES	CYANOSIS	PRECORDIUM	AUSCULTATION	ELECTRO-CARDIOGRAM	EXTRACARDIAC ASSOCIATIONS
Hypoplastic left heart	Weak, femoral stronger if DA open	Mild	Active	Gallop	Small LV voltages	Uncommon
Aortic arch interruption	Strong proximal to lesion	None	Active	Gallop, LVOT, systolic murmur	LV/RV1 T↓V ₅₋₆	Common (DiGeorge)
Coarctation	Weak femoral	None	Active	Gallop, EC, LVOT, systolic murmur Murmur between scapulae	RA1 RV1 T↓V ₅₋₆	Uncommon (Turner)
Critical aortic stenosis	Weak	None	Active	Gallop, EC, LVOT, systolic murmur	LV1 ST↓ T↓V ₅₋₆	Uncommon

DA, ductus arteriosus; LV, left ventricular; LVOT, left ventricular outflow tract; RV, right ventricular; EC, ejection click; RA, right atrial.

patients with delayed maturation and decreased head circumference documented on preoperative MRI scanning (Licht *et al.* 2009). The condition consists of a small left atrium, stenosis or atresia of mitral and aortic valves and hypoplasia of the left ventricle and aorta proximal to the DA (Fig. 28.20A). There is coarctation in 60–70% of cases. The right heart is dilated and hypertrophied with a large pulmonary artery. Head and coronary arterial flow is usually through retrograde filling of the transverse and ascending aorta via the DA.

Clinical features are given in Table 28.18. Before ductal closure occurs, femoral pulses may be stronger than upper limb pulses. The natural history is for collapse and subsequent demise to occur rapidly after ductal closure, usually between 5 and 10 days after birth. Occasional survival to a few months can occur with the systemic circulation dependent on continued patency of the arterial duct. The advent of prostaglandin and ultrasound and, more recently, fetal diagnosis has meant that most liveborn infants with HLHS can be stabilised whilst treatment options for this condition are considered.

Management of HLHS can involve staged palliative surgery (Norwood approach), transplantation or alternatively compassionate care if postnatal intervention is inappropriate for social or medical reasons. Transplantation in the UK and continental Europe is a limited treatment option because of a lack of donors. Staged palliation is now widely adopted as the most effective management with improving survival rates in many units (Edwards *et al.* 2007). Initial surgery is performed in the neonatal period and requires transection of the pulmonary trunk, which is then anastomosed to

the hypoplastic aorta, which in turn is augmented with a homograft patch. Supply to the detached pulmonary arteries is derived by placement of a systemic-to-pulmonary artery shunt (Fig. 28.20B) or a small RV to PA conduit. The first stage is followed by a superior cavopulmonary anastomosis at 4–6 months and completion of the cavopulmonary anastomosis at about 3 years to achieve a Fontan type of circulation (Fig. 28.20C, D). Survival for stage 1 is 80–90% in most specialist centres and is higher for the second and third stages. There is frequently a need for reintervention between stages and a continuing attrition in patients with this condition, as in all patients with a single-ventricle circulation. Furthermore, there is evidence to suggest that neurological outcome in patients managed with a Norwood protocol is not normal in a high percentage of cases (Wernovsky and Newburger 2003).

A number of centres have adopted a hybrid approach to first-stage management using a combination of catheter-based intervention with simultaneous surgery. This involves placement of a stent into the arterial duct to maintain patency and balloon atrial septostomy to ensure adequate-sized atrial communication. At the same time, bilateral branch pulmonary artery banding is performed to restrict pulmonary blood flow (Fig. 28.21). This avoids the need for cardiopulmonary bypass and circulatory arrest in the neonatal period when the immature brain is most susceptible to damage. Reported survival is good (Galantowicz *et al.* 2008), but it complicates the second-stage operation, which requires major aortic arch reconstruction as well as a superior cavopulmonary anastomosis. It has yet to be determined whether this approach will improve both survival and neurological outcome for patients with HLHS.

Fig. 28.20 Schematic representation of hypoplastic left-heart syndrome and the stages of surgical palliation. (A) The anatomy of hypoplastic left-heart syndrome (a, left ventricle; b, hypoplastic ascending aorta; c, large patent ductus arteriosus). (B) Norwood stage 1 operation (a, modified right Blalock–Taussig shunt; b, patch joining pulmonary artery with small aorta; c, patch to enlarge distal aortic arch).

(D) Total cavopulmonary connection (TCPC) using an extracardiac conduit between the inferior caval vein and pulmonary artery (a, oversewn inferior caval vein stump; b, Gortex tube anastomosed between detached inferior caval vein and pulmonary artery).

Critical aortic stenosis

This lesion lies at one end of a spectrum of severity of aortic valve abnormalities, the mildest of which may cause no symptoms even in adult life. It is commoner in males and the possibility of Turner syndrome must be considered in affected females. The aortic valve may have one, two or three cusps and there is often poststenotic dilatation of the ascending aorta. Aortic stenosis of any degree may be associated with some aortic regurgitation, mitral stenosis, VSD and coarctation. Symptomatic aortic stenosis at sub- or supra-valvar levels is rare in the newborn, but subvalvar aortic stenosis may develop in treated or untreated valvar aortic stenosis and in association with VSD and aortic coarctation or interruption. Progression of aortic stenosis and its unfavourable effect on the left ventricle in fetal life has been documented by ultrasound (Simpson and Sharland 1997). The evolution of fetal aortic valve disease has led to the use of prenatal cardiac interventional catheterisation to dilate the aortic valve in an attempt to promote left ventricular growth (Marshall et al. 2005). Success is limited, with the majority of patients ending up with a single-ventricle circulation despite what may be considered a successful intervention. Postnatally, the clinical picture depends on severity (Table 28.18) and ranges from an asymptomatic murmur with heart failure developing in early infancy to pulseless collapse when the DA shuts.

Angiography is not required for diagnosis, but cardiac catheterisation for balloon dilatation would be the treatment of choice in most centres, with surgical valvotomy reserved for failed valvuloplasty.

Survival is mainly determined by the state of the left ventricle, which may be dilated or severely hypertrophied. It is a matter of debate as to whether the most severe forms should be subject to Norwood-type surgery (see HLHS, above). The results after surgery and balloon dilatation are similar but recovery from dilatation is usually quicker (McCrindle et al. 2001). All infants requiring intervention in the newborn period will ultimately have further interventions for residual or recurrent stenosis or for aortic regurgitation.

Aortic arch interruption

This abnormality is present in 1% of congenital heart lesions. The DA supplies the descending aorta distal to the site of interruption, which is distal to the left subclavian artery in 30% (type A), between the left carotid and left subclavian arteries in 45% (type B) and between the innominate and left carotid in the remainder (type C). Approximately 50% of type A interruptions are associated with 22q11 deletion. Associated cardiac lesions always include VSD, often valvar or subvalvar aortic stenosis, sometimes mitral valve abnormalities, and very occasionally truncus arteriosus or aortopulmonary window. Clinical features are given in Table 28.18. Diagnosis can be strongly suspected clinically by careful attention to the pulses and is confirmed with clarification of associated lesions by ultrasound. Corrective surgery is usually performed through a median sternotomy with concurrent repair of intracardiac abnormalities, with up to 90% survival. Left ventricular outflow

Fig. 28.21 Schematic representation of a hybrid Norwood stage 1 procedure for hypoplastic left-heart syndrome with balloon atrial septostomy (a), bilateral branch pulmonary artery banding (b) and stenting of the arterial duct (c).

obstruction may progress even after successful neonatal surgery and often requires repeat surgical intervention; further intervention to the repaired aortic arch may also be required.

Coarctation

This makes up 10% of CHD, being more common in males but having a strong association with Turner syndrome, 15% or more of whom have the condition. The position of the discrete narrowing of the aorta is distal to the left subclavian artery, opposite the point of entry to the aorta of the DA (Fig. 28.15D). The exact position varies and may evolve in relation to ductal closure and postnatal growth. The terms pre-, juxta- and postductal are used to describe the site of coarctation and bear some relationship to the age of presentation and clinical picture.

Not all cases of coarctation cause symptoms in the newborn period or infancy; some remain asymptomatic for years or occasionally decades. When coarctation presents in neonates it is commonly associated with varying degrees of aortic arch hypoplasia, which may have implications for repair. Other lesions in the left heart are very commonly associated (mitral and aortic valve abnormalities), as are VSDs. Transposition and more complex cyanotic conditions may have accompanying coarctation. In the newborn with coarctation and PDA, there is systemic pressure in the right ventricle, although, until the DA starts to close, shunting is predominantly left to right at ductal and atrial levels. Thus, as heart failure develops, the infant is pink with RVH on ECG. When the duct shuts, some constriction of the descending aorta probably occurs, but is more critical in those babies who collapse. In others, duct closure is

tolerated, although heart failure and hypertension may occur in the early weeks of life. Those infants who remain asymptomatic in the newborn period may develop heart failure in later infancy with LVH on ECG. The time and mode of presentation of infants with associated intracardiac lesions are influenced by the nature of the associated lesion.

If the coexistent lesion presents early, great care must be taken not to overlook coarctation. Coarctation can be difficult to diagnose clinically (Table 28.18) in the newborn. Pulses and upper/lower limb BPs may be normal while the ductus is open, and, if collapse occurs, all pulses can be weak because of associated left ventricular dysfunction. Similarly, echocardiography imaging and Doppler assessment can sometimes be inconclusive whilst the ductus is wide open; even angiography and direct pressure measurements can be inconclusive. If there is doubt, careful observation and serial echocardiography over a period of a few days are required until the DA constricts and the characteristic features develop. Coarctation causing collapse is resuscitated with prostaglandin and heart failure is treated with diuretics.

Inotropic support is needed in critically ill infants and renal function must be watched carefully as occasionally renal failure develops. Infants who collapse or who are in heart failure should undergo surgical repair when stabilised. Coarctation as part of a more complicated lesion must be repaired before or at the same time as the intracardiac abnormality. In some circumstances, pulmonary artery banding is performed with coarctation repair if there is a cardiac lesion which will cause pulmonary plethora and which is not to be corrected in the newborn period, for example multiple muscular VSDs. There are disadvantages to pulmonary artery banding that mean it is desirable to avoid it if possible.

Coarctation in the newborn period may be repaired using the left subclavian artery (subclavian flap repair). This results in an absent brachial pulse in the left arm but very rarely leads to ischaemic problems there. Most surgeons prefer excision of the coarctation and end-to-end repair in newborns, as is the case after infancy. Mortality of coarctation repair without major intracardiac lesions is 5%. The recurrence rate may be as high as 20% in those repaired in the newborn period.

Conclusion

Any of the causes of collapse considered above may present less dramatically, usually with evidence of heart failure, which often precedes collapse. The precise diagnosis of which duct-dependent condition exists is not important at the resuscitation stage and, if a collapsed infant could have structural heart disease as the cause, prostaglandin should be given. This is likely to be rapidly therapeutic as well as helpful in confirming a cardiac cause for the collapse. Absence of response to prostaglandin at doses at the top of the range (Table 28.10) makes duct-dependent systemic circulation unlikely but not impossible. Risks of surgery are increased if renal or multiorgan failure is present.

Heart failure

Cardiac conditions presenting with heart failure are listed in Table 28.19 and clinical details given in Tables 28.20 and 28.21. Some of these conditions may present with collapse and in retrospect a period of respiratory distress may have been present prior to collapse. Cardiac conditions causing cardiac failure are invariably associated with respiratory distress (Table 28.17). Cardiac disease will also cause respiratory distress if there is marked pulmonary venous engorgement or metabolic acidosis has developed; these two occurrences can be associated with cyanotic cardiac conditions. Some

Table 28.19 Cardiac conditions presenting with neonatal respiratory distress

CATEGORY	COMMENTS
Heart muscle disease	
Ischaemia	With birth asphyxia
Myocarditis	Any cause
Cardiomyopathy	Hypertrophic or dilated
Arrhythmias	
Arteriovenous	Cranial or other with PPHN malformation
Structural heart disease	
Week 1	
Hypoplastic left heart	May also present with collapse
Interrupted arch	
Aortic atresia/critical stenosis	
Coarctation	
Obstructed TAPVC	
Tetralogy of Fallot with absent pulmonary valve	Symptoms due to airway obstruction by large PAs
Week 2–3	
Truncus	May also present with cyanosis
DOV, DIV, TAPVC	
TGA 1 VSD	
Week 3	
Left-to-right shunt lesions	Worse when multiple defects
VSD, AVSD, PDA etc.	
PPHN, persistent pulmonary hypertension of the newborn; TAPVC, total anomalous pulmonary venous connection; PA, pulmonary atresia; DOV, double-outlet ventricle; DIV, double-inlet ventricle; TGA, transposition of the great arteries; VSD, ventricular septal defect; AVSD, atrioventricular septal defect; PDA, patent ductus arteriosus.	

conditions characteristically cause both heart failure and cyanosis (Table 28.22). Signs of cardiac disease will be absent in respiratory causes of respiratory distress and a CXR usually allows the distinction to be made with confidence.

Arrhythmias (Table 28.20)

These are considered in detail on pages 661–663.

Heart muscle disease (Table 28.20)

There is little information on the incidence of heart muscle disease in the newborn, but cardiomyopathy is much more frequent under 1 year of age (about 8 per 100 000 per year) than in childhood overall (about 1 per 100 000 per year) (Lipshultz et al. 2003; Nugent et al. 2003).

Myocardial ischaemia

Subclinical myocardial ischaemia in asphyxiated and otherwise stressed infants is quite common (Barberi et al. 1999). Involvement severe enough to cause hypotension is less common, although a transient murmur from tricuspid or mitral regurgitation in association with ST depression and T-wave inversion in the left chest leads is a common finding. Specific therapy for heart failure is sometimes required; such infants usually have neurological and renal impairment in addition. Myocardial infarction in neonates may cause heart failure or sudden collapse. ECG changes include deep and wide Q waves and initial elevation of the ST segment, followed by T-wave inversion some days later. Q waves persist indefinitely but ST segment changes resolve in a week or so and T waves return to normal over a much longer timescale. Enzyme studies can be difficult to interpret in the early newborn period as other tissues may be the source of the enzymes and cardiac-specific isoenzymes need to be measured. Myocardial infarction can occur as part of generalised perinatal asphyxia or secondary to thromboembolic events (Tillett et al. 2001) and has a high mortality. Anomalous origin of the left coronary artery from the pulmonary artery is rarely symptomatic in the early weeks of life, as it is well tolerated whilst the pulmonary artery pressure remains high. It is a cause of pale sweating episodes (presumably angina), heart failure from dilated cardiomyopathy (DCM) and myocardial infarction after the newborn period. Ischaemia secondary to birth asphyxia usually recovers fully without any apparent long-term sequelae, even if intravenous inotropic support is required acutely. Long-term outlook after neonatal myocardial infarction is less well documented.

Myocarditis

Myocarditis is usually presumed and only occasionally definitely proven to be viral in origin, often in the context of a generalised viraemic illness (Kaski and Burch 2007). Heart failure and either tachy- or bradyarrhythmias can occur. Detection of a pericardial rub is rare in the newborn; pericardial effusion and even tamponade can occur. There is no specific therapy other than supportive measures: heart failure should be treated in the usual way, but digoxin used cautiously because of the risk of arrhythmias. The possible benefit in the use of steroids and immunoglobulin therapy for such cases remains unproven. Symptomatic, large or increasing pericardial effusions should be drained. Usually this is possible percutaneously. In some cases, neonates with suspected myocarditis have required extracorporeal membrane oxygenation support. Recovery of cardiac function occurs reasonably quickly if it is going to occur and there is an overlap between this group of patients and those who progress to DCM. Precise outcome figures are difficult to obtain because of this.

Dilated cardiomyopathy

This usually presents after the newborn period but fetal and neonatal presentation with heart failure does occur. Tachyarrhythmia must be excluded as a cause, as must anomalous origin of the left coronary artery, which is unlikely to present this young (see above). Detailed investigations for infective and metabolic causes are appropriate (Burch and Runciman 1996) (Table 28.23) if ischaemia or infarction is not clearly responsible.

If any of the screening investigations reveals possible aetiologies, enzyme studies on lymphocytes, fibroblasts or other tissue biopsies are indicated. If a metabolic cause is suspected from investigations or other clinical features such as skeletal myopathy, the question of blind treatment needs to be considered if the infant is critically ill.

Table 28.20 Clinical features of cardiovascular conditions not involving intracardiac structural abnormalities presenting with respiratory distress in the newborn

CONDITION	PULSES	PRECORDIUM	AUSCULTATION	ELECTROCARDIOGRAM	EXTRACARDIAC ASSOCIATIONS
Arrhythmia	Normal or weak	Normal	Gallop	Diagnostic	Rare
Heart muscle disease					
Myocarditis	Normal or weak	Normal	Gallop, MR murmur, rub	Small QRS ST↑, T↓	Common (e.g. hepatitis)
Ischaemia	Normal or weak	Normal	Gallop, MR murmur, TR murmur	ST↑, T↓	Features of perinatal asphyxia
DCM	Normal or weak	Normal	Gallop, MR murmur	LV+, ST↓↓, T↓↓	Rare
EFE	Weak	Normal or active	Gallop, MR murmur	LV+, ST↓↓, T↓↓ V ₅₋₆	Rare
HCM	Normal or jerky	Normal or active	Gallop, LVOT or RVOT	LV/RV+ ST↑ or T↓	Common (macrosomia, usually maternal diabetes)
Arteriovenous malformation					
Cranial	Normal or weak femorals	Active	Gallop, MR murmur, cranial bruit	LV/RV+ ST↓ or T↓	Neurological signs
Coronary	Full	Active	Gallop, continuous murmur	LV/RV+ ST↓ or T↓	

Note: Cyanosis is not present in any condition unless persistent pulmonary hypertension of the newborn occurs and all have cardiomegaly and pulmonary congestion on chest X-ray.
 DCM, dilated cardiomyopathy; LV, left ventricular; EFE, endocardial fibroelastosis; HCM, hypertrophic cardiomyopathy; LVOT, left ventricular outflow tract; RVOT, right ventricular outflow tract; AVM, arteriovenous malformation.

This may be appropriate if one of the carnitine deficiency states is suspected (Ino et al. 1988). First-degree relatives of infants with DCM should be evaluated clinically by ECG and echocardiography, as familial occurrence is recognised, even when precise metabolic diagnoses are lacking.

Endocardial fibroelastosis

This can be primary, in which case it has close clinical similarities to DCM, with marked left ventricular hypertrophy on ECG. The endocardium is echogenic on ultrasound. Endocardial fibroelastosis is often secondary to obstructive left-heart lesions, in which case the clinical picture and prognosis are influenced by the nature and severity of the accompanying pathology.

Hypertrophic cardiomyopathy

This can be primary, as a manifestation of an autosomal dominant genetic disease, or secondary, for example in association with Noonan syndrome (also autosomal dominant). Most common is hypertrophic cardiomyopathy (HCM) secondary to hyperinsulinism, usually maternal diabetes mellitus (Ch. 22). Infants receiving corticosteroids for CLD may develop reversible cardiac hypertrophy out of proportion to the degree of hypertension but they rarely show symptoms (Evans 1994). The majority of infants born to mothers with diabetes or gestational diabetes have no clinical

effects from HCM. Some have a left ventricular outflow murmur and a few develop respiratory distress attributed more often to impaired left ventricular filling than to outflow obstruction. It is often possible to demonstrate some tricuspid or pulmonary regurgitation in such infants, confirming a degree of pulmonary hypertension secondary to reduced left ventricular compliance in association with hypertrophy. Symptomatic infants may benefit from cautious beta-blocker therapy (because of the possibility of associated hypoglycaemia) and the hypertrophy will almost always resolve over a period of 1–2 months (Way et al. 1979). Inotropes are contraindicated in the cardiomyopathy of infants of diabetic mothers. Hypertrophy can be global or localised and this is reflected in the ECG and echocardiographic findings. Infants of diabetic mothers also have an increased incidence of structural heart disease (5%), making detailed assessment including echocardiography important if there are any cardiac symptoms or signs in such infants. If maternal glucose intolerance cannot be confirmed, a search for metabolic causes of cardiac hypertrophy is indicated (Table 28.23) (Way et al. 1979; Burch 1994; Guenthard et al. 1995).

Isolated left ventricular non-compaction

This form of left ventricular abnormality is now well recognised in children (about 10% of childhood cases of cardiomyopathy) and has been described in the fetus (Karatza et al. 2003).

Table 28.21 Structural heart lesions presenting with respiratory distress (heart failure) after the first week of life

CONDITION	PULSES	CYANOSIS	PRECORDIUM	AUSCULTATION	ELECTROCARDIOGRAM	EXTRACARDIAC ASSOCIATIONS
Truncus arteriosus	Normal or full	Mild	Active	S2 single, EC systolic	RV+ ± LV+ ST↓, T↓ V ₅₋₆	Common (DiGeorge)
TGA + VSD	Normal	Mild/moderate	RV+	S2 single ± VSD murmur	LV+ or RV+	Rare
TAPVC (unobstructed)	Normal or weak	Mild/moderate	RV+	S2 wide, P2 loud ± RVOT murmur	RV+ RsRVI	Rare
DIV/DOV without PS	Normal	Mild	Active	P2 loud VSD murmur	Variable	Rare
PDA	Full	None	Active	Continuous murmur at base	LV+ ± RV+	Occasional

RV, right ventricular; LV, left ventricular; TGA, transposition of the great arteries; VSD, ventricular septal defect; TAPVC, total anomalous pulmonary venous connection; RVOT, right ventricular outflow tract; DIV, double-inlet ventricle; DOV, double-outlet ventricle; PS, pulmonary stenosis; PDA, patent ductus arteriosus; AVSD, atrioventricular septal defect.

Left-to-right shunt lesions (Table 28.21)

These include both cardiac and extracardiac malformations. Traditionally, left-to-right shunts occur within the heart or great arteries but they can also develop outside the heart as AVMs. The left-to-right shunt associated with a significant-sized AVM can cause severe cardiac failure. In contrast to the left-to-right shunts that occur in the heart, the shunting through an AVM is not dependent on PVR and therefore symptoms of cardiac failure can develop early and in some cases are seen prenatally (see below).

Symptoms from significant intracardiac shunts do not develop until PVR falls enough to permit excessive pulmonary blood flow. This may happen slightly more quickly in preterm infants, related to the relative paucity of muscle in immature lung arterioles, but, even in premature babies, symptoms do not develop in the immediate perinatal period but may only become apparent after the first or second week of life. The most common site for intracardiac shunting is across the ventricular septum due to a VSD (Fig. 28.22).

In some circumstances, when the defect is large, PVR may not fall sufficiently to result in excessive lung blood flow. These infants

remain relatively well and pass into the phase of progressive vascular damage without heart failure occurring. Whether or not a period of heart failure occurs, the development of pulmonary vascular changes is universal and rapid in some lesions (e.g. complete AVSD) but unusual and not until adult life in secundum-type ASD. Other lesions lie between these extremes in both frequency and rapidity of progression to PVD. Extracardiac factors may influence the risk and hasten the development of PVD. These include extreme prematurity, CLD, airway obstruction, life at high altitude and Down syndrome.

Arteriovenous malformation (Table 28.20)

Arteriovenous fistulae may present in the newborn period with heart failure; there may be associated PPHN. Intracranial fistulae

Table 28.22 Structural cardiac conditions in which cyanosis and heart failure commonly coexist in the newborn

Transposition

- with coarctation
- with large VSD

Truncus arteriosus

Tricuspid atresia

- with large VSD
- with TGA and coarctation

Double-inlet ventricle

Total anomalous pulmonary venous connection

- with obstructed pulmonary veins

Hypoplastic left-heart syndrome with continued ductal patency

Arteriovenous malformation – usually intracerebral, often have PPHN

If significant pulmonary stenosis coexists, heart failure is unlikely and cyanosis is more marked.

VSD, ventricular septal defect; TGA, transposition of the great arteries; PPHN, persistent pulmonary hypertension of the newborn.

are the most common (aneurysm of the vein of Galen). Intrahepatic fistulae are occasionally encountered and may coexist with intracranial shunts. As well as heart failure, signs include a bruit over the affected site. Management consists of medical support for the circulation and intervention to stop or at least reduce the shunt through the AVM. This involves catheter embolisation for intracranial abnormalities, which are most commonly vein of Galen aneurysms. The outcome is determined by the ability to achieve a marked reduction in or abolition of the arteriovenous shunt and by the severity of secondary hydrocephalus and cerebral ischaemic lesions. Babies with an in utero diagnosis of AVM who have hydrops fare particularly badly.

Intracardiac left-to-right shunts

Patent ductus arteriosus

Prematurity and PDA are considered on [pages 645–647](#). As an isolated lesion outside the context of respiratory distress syndrome and prematurity, PDA accounts for nearly 10% of congenital heart lesions. Clinical features are given in [Table 28.21](#); diagnosis is often clinical and confirmed by echocardiography. PDA causing symptoms in term infants is an indication for closure. If the infant is asymptomatic without evidence of pulmonary hypertension, intervention is often delayed until later in infancy, when occlusion by catheter-delivered device or surgery is performed. The size at which catheter closure can be performed is being reduced all the time. Surgery and transcatheter closure both have high success rates and excellent long-term prognosis. The factors influencing which method is chosen are many and are evolving.

Atrial septal defect

Isolated ostium secundum ASDs very rarely, if ever, cause symptoms in newborn infants, but are occasionally suspected on auscultation. Left-to-right shunting at atrial level is often found on echocardiography either as an isolated finding or in conjunction with physiological pulmonary artery branch stenosis, PDA or more complex lesions. It is not always clear whether the shunt is through an ASD or merely through a PFO. Approximately 85–90% of atrial shunts detected by ultrasound in the newborn period disappear and defects sized <3 mm almost always do ([Radzik et al. 1993](#)).

Ventricular septal defect

VSDs without associated abnormalities account for at least 15% of structural heart lesions; up to 65% of them resolve spontaneously. They may be single or multiple and can occur in any part of the ventricular septum ([Fig. 28.21](#)). The site is of importance with respect to associated lesions, likely natural history and surgical approaches. Symptoms may never occur and, if heart failure does develop, it frequently does not do so until after the newborn period; indeed, there may be no murmur until several weeks of age. This is because there is little flow across a VSD whilst PVR is high. Diagnosis is usually clinical ([Table 28.21](#)) with echocardiographic confirmation and identification of precise location. Heart failure is treated as necessary ([Table 28.12](#)). Surgery is rarely needed in the newborn period unless there are associated lesions such as coarctation. Surgery is indicated for cases in which heart failure cannot be controlled to permit satisfactory weight gain. Surgical repair of VSD has a low mortality (<3%) even in the newborn period. Palliative pulmonary artery banding is only considered when there are multiple VSDs or if surgery is indicated for another lesion such as coarctation. When VSD is part of a more complex

lesion, strategies are different; in some circumstances a sizeable VSD is essential for satisfactory haemodynamics, for example in double inlet left ventricle with TGA.

Atrioventricular septal defect

The basic abnormality in this condition is in the AV septum, which in a normal heart separates the left ventricle from the right atrium. A defect here will always be associated with an abnormality of the AV valves. There may be an intra-atrial defect only (ostium primum ASD, termed partial AVSD), or additionally an intraventricular defect may also exist, in which case a complete AVSD is present and the AV valve has a single large orifice rather than two separate ones. In both forms there can be AV regurgitation, including left ventricular to right atrial shunting. Partial AVSD constitutes >2% of CHD and complete AVSD accounts for 2% of CHD. Either lesion can be part of the complex cardiac abnormalities found in left isomerism (partial AVSD) or right isomerism (complete AVSD), as described above. Partial AVSD is frequently undetected in the newborn period and may not cause heart failure in infancy, although surgical correction is required in childhood to prevent right-heart failure or PVD in adult life; cases with heart failure in infancy often have left AV valve regurgitation as well as left-to-right shunting at atrial level and require valve repair as well as surgical closure of the shunt.

Eighty per cent of cases of isolated complete AVSD are associated with Down syndrome; in the region of 35% of infants with Down syndrome and CHD have complete AVSD. Occasionally, tetralogy of Fallot coexists with AVSD, as may PDA or coarctation. In some cases of complete AVSD, one ventricle is much larger than the other (unbalanced AVSD); usually they are approximately equal sizes with volume overloading of the right ventricle. Clinical features of complete AVSD are given in [Table 28.21](#). Symptoms of heart failure may never develop as PVD can occasionally develop rapidly, particularly in Down syndrome. Therefore, it is desirable to make the diagnosis in the newborn period. It is for this reason and because signs can be subtle that at least an ECG (which is associated with a superior axis in AVSD) is useful and routine echocardiographic screening of all newborns with Down syndrome is indicated. Adequate information is obtained by echocardiography; angiography is not usually needed. Survival without surgery is not always beyond infancy, because of heart failure. However, of those alive at 1 year, survival into the late teens or twenties is common. Corrective surgery for cases detected in infancy improves outlook, with a surgical mortality of under 5%.

Aortopulmonary window

This rare abnormality involves a connection between the ascending aorta and the main pulmonary artery. It has haemodynamic and clinical features similar to large PDA and truncus arteriosus; it may coexist with PDA and with aortic arch interruption ([Table 28.21](#)). It can easily be overlooked on echocardiography, especially if a coexistent lesion is recognised. Surgical treatment at diagnosis is appropriate and has a high success rate.

Coronary arteriovenous fistula

This is another rare shunting lesion which presents with systolic and diastolic murmurs with or without bounding pulses and heart failure depending on the size of the shunt. The coronary fistula can be into any heart chamber or to the pulmonary artery. Ultrasound usually delineates the anatomy but angiography may be needed. Surgery or transcatheter occlusion is indicated for cases causing symptoms or signs in the newborn period. In many cases the fistula will become smaller or close spontaneously.

Conclusion

All the diseases and conditions discussed above may present in other ways such as asymptomatic murmurs and coincidental findings in investigations done for other reasons. In such circumstances, management will need to be tailored in the light of the clinical picture and likely natural history.

Cardiac conditions likely to present in the asymptomatic newborn (Table 28.24)

The commonest asymptomatic presentation of heart disease in the newborn period is the detection of a heart murmur, which may be a feature at an early stage of the natural history of many of the conditions discussed above.

Innocent heart murmurs

Detailed history and other features on physical examination are an important part of the evaluation of a heart murmur. The features of innocent murmurs in the newborn are given in [Chapter 14](#). It is important to note that innocent murmurs have positive characteristics as well as being associated with no other clinical evidence of cardiovascular disease. It is unclear whether ECG and CXR help the experienced or trained observer distinguish innocent from pathological murmurs ([Farrer and Rennie 2003](#)). Their widespread availability perpetuates their continued use. A practical approach following the detection of a heart murmur is given below.

Pathological asymptomatic heart murmurs

The likely causes for such murmurs detected in the newborn are given in [Table 28.24](#). The conditions listed are considered elsewhere in the chapter. As a general rule, obstructive lesions cause a murmur from birth, although the murmur associated with mild pulmonary stenosis, trivial aortic stenosis or simple bicuspid aortic valve may

not be heard. Pulmonary and particularly aortic stenosis may progress in severity. Lesions associated with left-to-right shunts frequently cause no murmur in the immediate newborn period and may not be detected until a 6- or 8-week routine check. If a pansystolic murmur suggesting VSD is heard in the newborn period, it may be due to tricuspid regurgitation, which will resolve over a matter of a few weeks. A VSD detected immediately after birth is likely to be small. If a structural abnormality is suspected as the cause of an asymptomatic murmur, an ECG and CXR should be performed. These investigations may have diagnostic features and are of some help in deciding the severity of the lesion and therefore timescale in which cardiology review and echocardiography are indicated.

Practical approach to neonatal heart murmurs

When a heart murmur is detected in the early newborn period, a number of options are open which will be influenced by local considerations, particularly availability of specialist cardiological services and echocardiography. The following are common approaches:

- If symptoms or other signs of cardiac disease exist, an ECG and CXR should be performed and cardiology referral made; this can involve the use of telemedicine to have the cardiac ultrasound assessed by a paediatric cardiologist prior to or instead of transferring the infant ([Casey 1999](#)).
- If no symptoms or other signs are present, but the murmur has features suggesting a structural lesion, an ECG and CXR should be performed and cardiology referral made.
- If no symptoms or other signs of cardiac disease are present and the murmur has features compatible with an innocent one, discharge from hospital is reasonable. Pulse oximetry should be performed (see above) in these babies prior to discharge from hospital. The family should be warned about important signs and follow-up arranged for 4–6 weeks. It has not been shown that ECG and CXR aid in this decision.

Table 28.24 Cardiac disease presenting in an asymptomatic newborn infant

CATEGORY	DETAIL	COMMENTS
Fetal diagnosis	Any cardiac condition	Diagnosis known/suspected before birth can be confirmed before symptomatic
Murmur	Causes include: Ventricular septal defect Tricuspid regurgitation Aortic stenosis Pulmonary stenosis Patent ductus arteriosus Atrial septal defect Arteriovenous septal defect Tetralogy of Fallot Innocent	
Weak femoral pulses	Coarctation	Many non-cardiac causes of weak pulses
Rhythm or rate abnormality	Fast/slow/irregular	Some are normal variants See arrhythmia section
Some cardiac conditions are diagnosed when cardiac assessment is requested following a non-cardiac diagnosis (e.g. neonatal surgical conditions or certain syndromes).		

Table 28.25 Features in an infant with a murmur which suggest the possibility of a serious (duct-dependent) lesion

FEATURE	COMMENT
No weight loss after birth or excessive weight gain, especially if feeding poorly	May suggest incipient heart failure
Any suggestion of symptoms/problems	If 'dusky', a transcutaneous hyperoxia test may help or pulse oximetry
Any doubt about quality of femoral pulses	Suggests coarctation
Right arm systolic blood pressure <20 mmHg above leg pressure	
Murmur loudest between scapulae	Suggests coarctation; innocent pulmonary murmur well heard front and sides
Cardiomegaly on chest X-ray	
Ventricular hypertrophy on electrocardiogram	

- In some centres, all babies with heart murmurs are referred for echocardiography (Ainsworth et al. 1999). This is not practicable in most UK services, and if the above approaches are adopted consistently, the likelihood of a baby with serious cardiac disease coming to harm through delayed diagnosis is small (Farrer and Rennie 2003).

A baby with an asymptomatic murmur should not be allowed home until it is clear that no form of duct-dependent CHD is present; this is usually apparent on clinical grounds (Table 28.25). If there is any doubt, either a further period of observation in hospital is indicated or, preferably, echocardiography should be arranged.

Arrhythmias

In the newborn, primary cardiac arrhythmias requiring treatment are uncommon. Tachy- or bradyarrhythmias are much more likely to be secondary to extracardiac pathology, which must be identified and treated. Occasionally sustained tachyarrhythmias can present with cardiac failure or collapse secondary to impaired cardiac function caused by the arrhythmia. Gaining control of the arrhythmia will usually result in gradual return of normal cardiac function.

Recognition of arrhythmias

Infants with an arrhythmia may be asymptomatic or present with heart failure or very rarely with collapse. Some will have been recognised in utero. An ECG will usually allow precise diagnosis, although occasionally this will not be possible either because the abnormal rhythm is intermittent or because the ECG is difficult to interpret. Sinus rhythm exists if each QRS complex is preceded by a P wave with an axis of 0–190° and with a normal PR interval (90–120 ms). An approach to assessing the ECG in a possible arrhythmia involves answering the questions given in Table 28.26.

Table 28.26 Approach to electrocardiogram interpretation of an arrhythmia

QRS complexes	Rate	Slow/norm/fast
	Rhythm	Regular/irregular If irregular: premature/delayed
	Configuration	Normal/abnormal
P waves	Seen/not seen	
	Rate	Slow/normal/fast
	Rhythm	Regular/irregular If irregular: premature/delayed
	Axis	Normal/abnormal
	Relationship to QRS complexes	None/constant/variable If constant: before/within/after
		If before, PR interval: Normal/long Fixed/changing

Arrhythmias can be classified in a number of ways. They will now be considered under the headings either supraventricular or ventricular. There are important normal variations in rhythm and rate (Southall et al. 1980), which are mentioned at appropriate points below.

Sinus bradycardia

When asleep or when straining, the interval between QRS complexes can lengthen transiently up to 1.5 s, but sustained rates, even during sleep, below 80 beats/min in term or 100 beats/min in preterm infants are not normal. Sinus bradycardia is associated with normal P waves before every QRS complex; the complexes are normal unless the cause of the bradycardia has other effects on the myocardium. Sinus bradycardia is seen most commonly in association with apnoeic episodes. It may also be a manifestation of hypoxaemia, raised intracranial pressure of any cause and hyperkalaemia. It is seen in association with stress from handling and interventions in critically ill infants. Drugs may cause sinus bradycardia, for example heavy sedation administered to the infant or before birth to the mother, digoxin, propranolol and corticosteroids. Sustained sinus bradycardia in a relatively well infant is a feature of hypothyroidism.

Sinus arrhythmia and sinus arrest

These result in variable slowing of the heart rate. Neither is common in the newborn infant. Sinus arrhythmia is an increase in the heart rate during inspiration and results in a regular irregularity of heart rate in time with the respiratory cycle. Sinus arrest or pauses result in an occasional abnormally long pause (<1.6 s) between P waves, producing an irregular irregularity of the heart rate. These two variations of normal are of no significance of themselves. If they are very pronounced, they can be a marker of sinoatrial dysfunction, which may be associated with symptomatic bradycardia or tachycardia.

Atrial ectopics

These are due to premature depolarisation of a site in an atrium earlier than the sinus node discharge so that either a premature QRS complex follows or, if the ectopic is so early as to occur whilst the ventricle is in its refractory period, there is no QRS complex (blocked

atrial ectopics; Fig. 28.23). Intermediate between these two timings for the atrial ectopic, a QRS complex will be conducted aberrantly and be broad. If non-conducted atrial ectopics occur regularly alternating with normally conducted sinus impulses, there will be bradycardia in the region of 60–80 beats/min. If ectopics are frequent or non-conducted but not alternating with sinus beats, the heart rate will be irregular (Fig. 28.23). Atrial ectopics are harmless but may cause confusion when detected in the fetus, causing bradycardia with or without an irregular rhythm. They can be correctly diagnosed by fetal ultrasound and thereby prevent unnecessary concern about fetal wellbeing being engendered. They are markers for an increased incidence of SVT, which may not necessarily be symptomatic. Atrial ectopics resolve within 3 months in 90% of cases.

Sinus tachycardia

Sinus tachycardia is a heart rate above 160 beats/min in term and above 180 beats/min in preterm infants. P waves have a normal axis and precede every QRS complex. Sinus tachycardia is always secondary, usually to a non-cardiac cause. Causes to be considered include fever, hypovolaemia, pain, respiratory failure, anaemia, fluid overload, drugs (in particular, methylxanthines and inotropes) and septicæmia. Structural heart disease or heart muscle disease may cause sinus tachycardia. The cause should be identified and treated; therapy for sinus tachycardia itself is not indicated. In the newborn, sinus tachycardia can reach 230 beats/min, so that at its higher rates it can be difficult to distinguish from the pathological types of SVT.

Supraventricular tachycardia

A simple classification of SVT is given in Table 28.27.

Atrial flutter

This is a rare rhythm in the newborn. It may be diagnosed in utero, in which case maternal digoxin and/or flecainide therapy is indicated. There is an association with myocarditis, myocardial ischaemia and structural heart disease, although the heart is often structurally normal in neonates. Atrial rates usually exceed 300 beats/min and ventricular rate and rhythm will vary with the degree and constancy of AV block. Consistent 2:1 AV block can make the rhythm hard to recognise as the characteristic flutter waves are

hidden by QRS complexes. They may become apparent when the degree of block varies spontaneously or with adenosine administration. Fetal or neonatal heart failure often develops. The rhythm can be well tolerated for short periods but attempts to restore sinus rhythm or at least to control ventricular rate are appropriate to prevent deterioration in heart muscle function. Adenosine will not restore sinus rhythm but may transiently increase AV block, allowing a diagnosis to be made if the rhythm has not been recognised prior to its use (Fig. 28.24). Shocked infants and those in heart failure warrant direct-current (DC) cardioversion to establish sinus rhythm; this should not be carried out without sedating the infant. Recurrence after cardioversion by either of these techniques may occur but is less likely in the newborn than in older children. Digoxin is used to slow ventricular rate and to help maintain sinus rhythm when achieved. Propranolol may be added to digoxin therapy to achieve further control of ventricular rate. If immediate restoration to and maintenance of sinus rhythm cannot be achieved, the outlook is still good, with spontaneous recovery, if ventricular rate and therefore symptoms can be controlled. Preventive antiarrhythmic therapy after early infancy is not required. A minority of patients have an underlying pre-excitation ECG and in many there is probably an underlying accessory pathway. The arrhythmia carries a small mortality in the newborn either from intractable heart failure or from progression to more malignant arrhythmias, spontaneously or in response to electrical or pharmacological intervention.

Atrioventricular re-entry tachycardia

This is the commonest form of SVT in the fetus and newborn and is associated with the presence of an accessory AV conduction pathway. Fetal SVT can be treated by administration of digoxin, flecainide or verapamil to the mother (Allan et al. 1991; Simpson and Sharland 1998) in specialist centres. Administration of antiarrhythmics directly to the fetus is occasionally used. It is preferable to bring the arrhythmia under control before delivery, but in some circumstances this will not be possible. It is almost always possible to achieve rate control prior to delivery. An attempt to gain control of the arrhythmia or achieve rate control is always indicated prior to considering premature delivery. Premature infants tolerate arrhythmias significantly less well than their term counterparts.

The ECG in sinus rhythm may have a pre-excitation pattern (short PR interval and delta wave on QRS upstroke), allowing Wolff-Parkinson-White syndrome to be diagnosed. Even if present, a pre-excitation pattern may be intermittent or disappear with age. The QRS complexes are narrow when SVT occurs unless aberrant conduction occurs, which is very unusual in the newborn. P waves may be visible between QRS complexes, but, if they are, they have an abnormal axis. QRS rates vary from 180 to 300 beats/min (Fig. 28.7). Distinction from sinus tachycardia is occasionally difficult but the overall clinical picture usually allows this, as well as careful examination of the ECG for features mentioned above. Infants can be asymptomatic or have episodes of pallor and breathlessness or be in heart failure. Any form of structural heart disease, myocardial tumours, myocarditis, electrolyte disturbances or indwelling right atrial lines should be considered as causes, but the heart is usually normal. Myocardial dysfunction and mitral regurgitation develop secondary to the arrhythmia and can be expected to resolve once rhythm control is achieved. If the clinical condition allows, facial immersion in cold water until conversion or for a maximum of 10 seconds is associated with an 85–90% cardioversion rate (Sreeram and Wren 1990). If this fails or is impracticable, application of ice to the face may be tried but has a lower success rate, and adenosine

Table 28.27 Simple classification of supraventricular tachycardia

SITE	RHYTHM	COMMENT
Sinus node	Sinus tachycardia	Always secondary
Atrium	Atrial flutter	Rare
	Atrial fibrillation	Very rare
	Atrial tachycardia	Uncommon

	AV nodal re-entry	Rare
	Tachycardia	
Below AV node	His bundle tachycardia (junctional ectopic tachycardia)	Very rare Usually postoperative
AV, atrioventricular.		

intravenously should be used. Adenosine also has an 85% success rate in restoring sinus rhythm and it may unmask atrial flutter if present.

Contraindications to adenosine in the newborn are few. Dipyridamole will potentiate its effects. Side-effects include transient profound bradycardia. If these measures fail and the baby is collapsed, synchronised DC shock should be given, starting at 1 J/kg and increasing to a maximum of 3 J/kg. If rhythm control is not achieved, then starting an amiodarone infusion will usually reduce the rate over time and further attempts to cardiovert the baby using adenosine or DC shock 4–8 hours after starting amiodarone can be undertaken. Verapamil is not recommended for intravenous administration in the newborn period or infancy because of the incidence of bradycardia and hypotension associated with its use. In summary, acute treatment of SVT is as follows (drug doses are given in Table 28.28):

- DC cardioversion if collapsed (sedate unless unconscious).
- Facial immersion/icebag.
- Intravenous adenosine if vagotonic manoeuvre fails.
- Review need for cardioversion. Retry facial immersion and intravenous adenosine if DC cardioversion still not indicated.
- If in heart failure, observation is not appropriate and amiodarone should be considered in conjunction with discussion with cardiology service.
- When sinus rhythm is established, decide on appropriate maintenance–preventive treatment (see text).

Once sinus rhythm is restored, maintenance therapy with whatever agent(s) restored is usually given for about 3–6 months. Drug doses are given in Table 28.28. SVT which presents prenatally or in the neonatal period will resolve spontaneously during the first year of life in the majority of cases.

Ventricular arrhythmias

Ventricular arrhythmias have QRS–T complexes which are always different in configuration and polarity from those in sinus rhythm; the QRS complexes are usually, but not necessarily, broad. Broad complexes can be hard to recognise in the newborn as the upper limit of normal for QRS duration is only 70 ms. Associated and causative conditions for ventricular arrhythmias include any type of cardiomyopathy, myocarditis, intracardiac tumours, electrolyte disturbances, hypoxaemia and acidosis, and only rarely structural CHD. Familial long-QT syndromes (Schwartz et al. 1993) may be detected in the newborn if the family history is known or if ventricular arrhythmias occur.

Premature ventricular complexes

These are recognised by being abnormal premature QRS complexes without a preceding P wave. They are followed by a compensatory pause. Sometimes, complexes with features of both the ventricular ectopic (VE) and the normal QRS complex are seen (fusion complexes). VEs have been found in up to 33% of healthy newborn infants (Southall et al. 1980). They are rarely a sign of cardiac disease but the conditions listed above must be considered. Occasional unifocal VEs with normal clinical examination and ECG require no action in the newborn period, merely review at 6–8 weeks. Very frequent VEs, the presence of a family history suggesting a long-QT syndrome, cardiac physical signs or ECG abnormalities – particularly a long QT (Villain et al. 1992) or evidence of heart muscle disease – are an indication for echocardiography and 24-hour ECG monitoring (looking for VT). Isolated VEs with a

normal heart require no treatment and will resolve within 2 months; if they do not, echocardiography and 24-hour ECG monitoring should be performed or repeated.

Ventricular tachycardia

This is rare in the newborn and consists of a series of VEs occurring sequentially with a rate of 150–250 beats/min. Close examination reveals that there are almost always minor irregularities in rate and that the P waves, if recognised, are either dissociated from the QRS complexes or conducted retrogradely. The rhythm may be paroxysmal or sustained; if paroxysmal, fusion beats may be seen. Neonates with VT may have underlying diseases as listed above but may have normal hearts. A well infant with no underlying disease may be asymptomatic; most cardiologists would still advocate preventive treatment in such cases initially. Collapsed infants should receive synchronised DC shock; less severely symptomatic infants should be treated with lidocaine or amiodarone intravenously. Pulseless VT should be treated with full cardiopulmonary resuscitation and DC shock (1–2 J/kg). If the rhythm reflects underlying electrolyte disturbance, this should be rapidly corrected. Propranolol is the traditional oral preventive; amiodarone may be used in certain cases (Table 28.28).

Idioventricular rhythm

This has the morphology of VT but is slower (110–120 beats/min), being around the same speed as sinus rhythm. It is rarely a sign of heart disease, is usually well tolerated and has a benign natural history.

Ventricular fibrillation

The QRS complexes are fast, bizarre and irregular. Full cardiopulmonary resuscitation should be instituted if the underlying pathology is unknown or considered remediable. Ventricular fibrillation is very rare in neonates and is usually terminal whatever the cause. If controlled, long-QT syndrome must be excluded.

Atrioventricular conduction disturbances (heart block)

There are three degrees of AV conduction block.

First-degree heart block

This is present when the PR interval exceeds the upper limit of normal for age and heart rate; the maximum is 110 ms in the newborn. It is never symptomatic but may reflect underlying structural heart disease such as ASD, heart muscle disease or drug effect (for example, digoxin). It can occur in families and may progress to more severe degrees of block.

Second-degree heart block

This is present when not every P wave is followed by a QRS complex. There are two forms. Mobitz type I second-degree AV block shows the Wenckebach phenomenon in which the PR interval progressively increases until, after three to six cycles, the P wave is not conducted; the sequence then commences again. This phenomenon may be normal and is seen in sleep or under anaesthesia at any age and does not necessarily reflect underlying heart disease. Mobitz type II block has a fixed normal or long PR interval with intermittent non-conduction of the P wave. Failure to conduct the P wave

Table 28.28 Antiarrhythmic drug doses

DRUG	DOSE AND ROUTE	COMMENT
Adenosine	0.05–0.25 mg/kg rapid i.v.	Start low and increase at 2-minute intervals
Digoxin	10 µg/kg i.v. over 15 minutes, then 5 µg/kg i.v. after 6 hours; repeat after a further 6 hours After digitalisation regimen start maintenance at: 4 µg/kg/dose oral 12-hourly (give 60% of this if using i.v. route)	Acute loading doses. Ensure infant is not hypokalaemic
Propranolol	0.05 mg/kg i.v. over 2 minutes 1–2 mg/kg/dose oral 8-hourly	Acute, may repeat once. Avoid in severe heart failure Beware hypoglycaemia Never use after verapamil
Amiodarone	i.v. load with 25 µg/kg/min and titrate dose to heart rate Oral 5 mg/kg t.d.s. and decrease to b.d. then o.d. at 7 and 14 days Respectively (maintain on o.d.)	Ideally via central access Oral not suitable for acute prescription
Verapamil		Better avoided in newborns Never use after propranolol
Lidocaine	1 mg/kg i.v., then 1 mg/kg/h i.v.	
DC shock	SVT (synchronised) 0.5–1 J/kg VT/VF 1–2 J/kg	Sedation/anaesthesia required unless infant unconscious
Note: Other drugs used vary with local expertise. Advice should be sought. DC, direct current; SVT, supraventricular tachycardia; VT, ventricular tachycardia; VF, ventricular fibrillation.		

is often at regular intervals such as 2:1, 3:1 and so on. Mobitz type II block is much more likely to reflect underlying cardiac disease and frequently progresses to CHB.

Third-degree heart block

This is also termed CHB. The P waves and QRS complexes in CHB are totally dissociated. The atrial rate and responsiveness are usually normal and the ventricular rate is usually between 40 and 80 beats/min with limited variation (Fig. 28.19). Fetal and neonatal CHB may be associated with a variety of usually complex structural heart lesions, in which case heart failure is the norm and outlook is frequently poor.

Another group of patients with congenital CHB have structurally normal hearts. A high proportion of these infants have His bundle fibrosis secondary to maternal antibodies, termed anti-Ro or -La antibodies. Mothers with these antibodies may have connective tissue disorders but more usually are well with serological markers for connective tissue disease. Many neonates with normal hearts and CHB are asymptomatic. Heart failure may occur pre- or post-natally; Stokes–Adams attacks are rare. A number of factors identify infants likely to have a poor outlook without intervention; these include structural heart disease, symptoms, resting heart rate below 55 beats/min, little increase in heart rate in response to stress and broad QRS complexes. If necessary, specific emergency management should include inotropes and diuretics and, if possible, temporary transvenous pacing. Permanent pacemaker insertion is invariably epicardial in newborn infants. CHB in the fetus is usually well tolerated with a structurally normal heart; if hydrops starts to develop, thought should be given to delivery. However, the complications of transvenous pacing in premature and low-birthweight infants should not be underestimated. Evidence that the fetal heart rate can

be significantly increased by drug administration to the mother is unclear; maternal steroid administration to prevent His bundle damage has been advocated but is not universally accepted. Fetal pacemaker insertion has yet to be successful.

Hypertension

Hypertension in newborn infants is primarily of renal origin, although cardiac, endocrine and pulmonary causes have been described (see Table 28.29). The incidence of hypertension in newborns is low – 0.2–3%. BP in newborn infants is influenced by gestational age, birthweight and postconceptual age. Data from Zubrow *et al.* (1995) are the most widely used measures with the BP considered elevated if it falls above the 95% confidence limits for infants of similar age and size (Appendix 4). As a useful rule of thumb, a systolic BP above 90 mmHg and certainly above 100 mmHg in a term baby should be evaluated carefully. In most newborns, hypertension is discovered on monitoring of vital signs. Measurement of neonatal BP is discussed on page 630.

Critically unwell infants are likely to have direct invasive BP measurements. Causes of hypertension are given in Table 28.29. Hypertension is rarely symptomatic but may cause heart failure, tachypnoea, poor feeding, irritability and other neurological signs. In premature babies, a history of CLD and indwelling umbilical arterial or venous catheters may be relevant. Thromboembolism causing renovascular hypertension is surprisingly common after umbilical arterial catheterisation and is thought to be related more to umbilical arterial endothelial damage at the time of line placement than the position of the catheter (high versus low). CLD with bronchopulmonary dysplasia may cause hypertension in 40% of infants (Abman *et al.* 2002) but the hypertension does not usually present until after discharge from the neonatal units.

Table 28.29 Causes of neonatal hypertension

SYSTEM	EXAMPLES	COMMENT
Renal	Renal artery emboli/thrombosis Renal vein thrombosis Dysplastic renal disease Urinary tract obstruction Renal infection Renal failure	May be UAC-related May be acutely symptomatic Often improves over 12 months Hypertension may be delayed-onset Any cause
Cardiovascular	Coarctation	
Endocrine	Congenital adrenal hyperplasia Hyperaldosteronism Hyperthyroidism Pheochromocytoma Neuroblastoma	
Respiratory disease	Acute hypercapnia Chronic lung disease	Any cause Often steroid-induced
Neurological disease	Raised intracranial pressure Convulsions	Any cause Treating blood pressure alone will reduce cerebral perfusion pressure Probably mediated via intracranial pressure, convulsion may be subtle or masked by drugs
Drugs	Neonatal exposure: Corticosteroids Methylxanthines Phenylephrine Inotropes Fetal exposure: Maternal cocaine	In eye drops Overdose

Examination should look for dysmorphic features to exclude genetic syndromes and move on to four-limb BP measurements to look for aortic coarctation. After cardiovascular examination, abdominal assessment to exclude obvious renal abnormalities (e.g. large polycystic kidneys) and genital examination to exclude congenital adrenal hyperplasia are important. Routine investigation should include standard serum biochemistry with thyroid function tests, plasma cortisol, aldosterone and rennin levels. Ultrasound imaging to exclude coarctation and evaluation of the kidneys and renal blood vessels is essential. Renal angiography is not usually required in the neonatal period. Renal perfusion imaging is also less accurate in neonates because of immature renal function and needs to be interpreted with caution.

Specific treatment is appropriate if there are symptoms; in their absence, therapy should be aimed at the underlying disease and hypotensive therapy only commenced if there is severe hypertension or evidence of progressive left ventricular hypertrophy. Some drugs and dosages commonly used to treat neonatal hypertension are listed in [Tables 28.30 and 28.31](#). In the rare circumstances where intravenous antihypertensive therapy is required, intravenous infusions of diazoxide, hydralazine, sodium nitroprusside, labetalol, esmolol or nicardipine can be used. Rapid reduction of BP can also be achieved using oral ACE inhibitors (captopril) or oral nifedipine. There are concerns about possible adverse effects of captopril on renal development in neonates and oral nifedipine is difficult to

administer in small doses. Long-term beta-blockers may not be suitable in patients with bronchopulmonary dysplasia but, often, both hypertension and pulmonary compliance are improved with long-term diuretic therapy. Alternative drugs used for longer term therapy include minoxidil, clonidine and amlodipine amongst others.

The prognosis in hypertension is that of the underlying cause, providing malignant hypertension is avoided or treated rapidly and effectively. Encephalopathic infants may need sedation or anticonvulsant medication as well as hypotensive therapy, but hypertensive encephalopathy is remarkably rare in the newborn.

Cardiac tumours

Symptomatic cardiac tumours are extremely rare in the newborn but are found more commonly since the widespread use of ultrasound scanning. So-called golfball tumours or echogenic foci, usually in the left ventricle, are isolated fetal echocardiographic findings which have usually resolved by term and are of no functional significance. They do not significantly increase the risk of a syndrome even if found in both ventricles ([Simpson 1999](#)). Post-natal follow-up is not required.

Cardiac tumours in the newborn may cause arrhythmias ([Muhler et al. 1994](#)) or, less commonly, physical obstruction within the

Table 28.30 Intravenous drugs for treating systemic hypertension

DRUG	CLASS	INTRAVENOUS (I.V.) DOSAGE	COMMENTS
Diazoxide	Vasodilator (arteriolar)	2–5 mg/kg/dose rapid i.v. bolus	Slow i.v. injection ineffective; duration unpredictable; use with caution, may cause rapid hypotension; increases blood glucose
Esmolol	Beta-blocker	100–300 µg/kg/min i.v. infusion	Very short-acting; constant i.v. infusion necessary
Hydralazine	Vasodilator (arteriolar)	0.15–0.6 mg/kg/dose i.v. bolus or 0.75–5 µg/kg/min i.v. constant infusion	Tachycardia is frequent adverse effect; must administer over 4 hours when administered as i.v. bolus
Labetalol	Alpha-blocker and beta-blocker	0.2–1 mg/kg/dose i.v. bolus or 0.25–3 mg/kg/h i.v. constant infusion	Heart failure, bronchopulmonary dysplasia, relative contraindications
Nicardipine	Calcium channel blocker	1–5 µg/kg/min i.v. constant infusion	May cause reflex tachycardia
Sodium nitroprusside	Vasodilator (arteriolar and venous)	0.5–10 µg/kg/min i.v. constant infusion	Thiocyanate toxicity can occur with prolonged use (>72 hours) or in renal failure; usual maintenance dose <2 µg/kg/min, may use 10 µg/kg/min for short duration (i.e. <10–15 min)

Table 28.31 Drugs for treating systemic hypertension

DRUG	CLASS	ORAL DOSAGE	COMMENTS
Captopril	ACE inhibitor	<3 months: 0.01–0.5 mg/kg/dose three times daily; not to exceed 2 mg/kg/day ≥3 months: 0.15–0.3 mg/kg/dose three times daily; not to exceed 6 mg/kg/day	Monitor serum creatinine and potassium levels
Clonidine	Central agonist	0.05–0.1 mg/dose 2–3 times daily	Adverse effects include dry mouth and sedation; rebound hypertension with abrupt discontinuation
Hydralazine	Vasodilator (arteriolar)	0.25–1 mg/kg/dose t.i.d. q.i.d.; not to exceed 7.5 mg/kg/day	Suspension stable up to 1 week; tachycardia and fluid retention are common adverse effects; lupus-like syndrome may develop in slow acetylators
Amlodipine	Calcium channel blocker	0.1–0.3 mg/kg/dose b.i.d.; not to exceed 0.6 mg/kg/day or 20 mg/day	Less likely to cause sudden hypotension than isradipine
Minoxidil	Vasodilator (arteriolar)	0.1–0.2 mg/kg/dose 2–3 times daily	Most potent oral vasodilator; excellent for refractory hypertension
Propranolol	Beta-blocker	0.5–1 mg/kg/dose three times daily	Maximal dose depends on heart rate; may administer as much as 8–10 mg/kg/day if no bradycardia; avoid in infants with bronchopulmonary dysplasia
Labetalol	Alpha- and beta-blocker	1 mg/kg/dose 2–3 times daily, up to 12 mg/kg/day	Monitor heart rate; avoid in infants with bronchopulmonary dysplasia
Spironolactone	Aldosterone antagonist	0.5–1.5 mg/kg/dose twice daily	Potassium-sparing diuretic; monitor electrolytes; several days necessary to observe maximum effectiveness
Hydrochlorothiazide	Thiazide diuretic	2–3 mg/kg/day orally every day or divided twice daily	Monitor electrolytes
Chlorothiazide	Thiazide diuretic	5–15 mg/kg/dose twice daily	Monitor electrolytes
ACE, angiotensin-converting enzyme.			

heart. Over 95% of intracardiac tumours in the newborn are benign and at least 75% of them are rhabdomyomata. Rhabdomyomata are often multiple and may resolve, which is a reason for being cautious about surgical intervention even if symptoms are present (Muhler et al. 1994). Multiple intracardiac tumours strongly suggest the possibility of tuberous sclerosis; 50% of individuals with tuberous sclerosis will have cardiac tumours detected by echocardiography if looked for in infancy (Wallace et al. 1990). Pericardial

tumours may present with pericardial effusion and tamponade in the newborn period.

Acknowledgement

The author and editor would like to acknowledge the contribution of Dr Nick Archer, author of this chapter in previous editions, for his excellent foundation.

Part 1: Neonatal jaundice

N Kevin Ives

Introduction

Jaundice is the most common clinical sign in neonatal medicine. Approximately 60% of healthy term infants and 80% of premature infants develop clinically visible jaundice in the first week of life, but only rarely is it the harbinger of significant disease or associated with bilirubin neurotoxicity. In the majority of cases jaundice is mild and transient, resulting from an immaturity of the liver's excretory pathway for bilirubin at a time of its heightened production. Neonatal jaundice remains one of the most common reasons for readmission to hospital in the first week of life. Prolonged jaundice, beyond 2 weeks of life in the term infant, is common and usually innocent, but may be a warning sign of underlying disease.

Up to a third of breastfed babies are clinically jaundiced at 2 weeks of age. Screening for significant jaundice in the first days and weeks of life needs to be in place so that pathological causes are diagnosed promptly and treated appropriately. The importance of identifying conjugated hyperbilirubinaemia at an early stage cannot be overstressed.

With relaxation of treatment thresholds for jaundice over the past two decades a 'kinder, gentler approach' to clinical management in healthy full-term newborns has evolved (Newman and Maisels 1992). This spared a large number of babies and their families the stress of blood tests, phototherapy, exchange transfusion and prolonged hospitalisation (Seidman et al. 2001), but a less vigilant approach to the jaundiced infant may have been engendered. Earlier

postnatal discharge, inadequate community surveillance and translation of the more relaxed approach to therapy in the term baby to that in the late preterm or near-term infant led to a resurgence of kernicterus, as noted in Europe and the USA (Newman and Maisels 2000; Watchko 2001; Ives 2007; Manning et al. 2007).

Our ability to identify which babies are at greatest risk of developing levels of significant jaundice remains imprecise. The American approach has been to focus on the predictive value of an hour-specific predischarge bilirubin measurement (Bhutani et al. 1999; Maisels et al. 2009a). Recent national guidance in the UK, where discharge at less than 24 hours is becoming the norm, mandates review within 48 hours of birth of babies with risk factors, and recommends measurement of the bilirubin level in all babies presenting with clinical jaundice (National Institute for Health and Clinical Excellence 2010).

Phototherapy remains the mainstay of treatment of significant unconjugated hyperbilirubinaemia, and its optimal use will usually keep the level of jaundice below the threshold for a potentially hazardous exchange blood transfusion. In cases of isoimmune haemolysis high-dose immunoglobulin is indicated if the serum bilirubin is continuing to rise despite optimal phototherapy (Gottstein and Cooke 2003; National Institute for Health and Clinical Excellence 2010). The use of metalloporphyrins to suppress haem catabolism and modify the pattern of neonatal jaundice has not yet entered routine clinical practice.

Bilirubin biochemistry

Bilirubin is produced by a two-stage catabolism of haem in the reticuloendothelial system (Fig. 29.1). The majority of haem arises from the turnover of haemoglobin released from naturally decommissioned or pathologically destroyed erythrocytes. Haem (ferroprotophyrin IX) has a porphyrin ring structure which is opened preferentially at its α -methene bridge by haem oxygenase. The intermediate pigment, biliverdin IX α , is water-soluble, non-toxic and serves as the excretory product of haem in amphibians, reptiles and birds. In mammals, reduction of biliverdin IX α by biliverdin reductase results in the production of bilirubin IX α .

Bilirubin IX α is the only toxic isomer of bilirubin. The small amounts of the IX β and IX δ isomers produced are non-toxic. Why mammalian species should expend energy producing and excreting a potentially neurotoxic haem byproduct remains unclear. One possible explanation stems from the fact that bilirubin is an antioxidant, prompting the question: 'Is bilirubin good for you?' (McDonagh 1990). Whatever the reason, we are left with the responsibility of ensuring that serum levels of free bilirubin IX α fail to reach neurotoxic levels.

Diagrammatic representation of the bilirubin molecule gives the impression of a tetrapyrrole aligned in a single plane (Fig. 29.2), but the preferred conformation of the molecule is partially folded

Fig. 29.1 Production of bilirubin from haem degradation.

at its mid-methylene bridge (Fig. 29.3). This shape facilitates intramolecular hydrogen bonding, saturating the hydrophilic polar groupings, and rendering bilirubin virtually insoluble in water at physiological pH. In this form, bilirubin has lipophilic properties, enabling it to cross cell membranes and biological boundaries, such as the placenta and blood–brain barrier.

Fig. 29.2 Linear representation of bilirubin IX α with central propionic acid groups (**).

Fig. 29.3 (A) Preferred conformation of bilirubin. (B) Atomic representation of the bilirubin-IX α ZZ molecule (nitrogen, mid-grey; oxygen, dark grey; carbon, light grey; hydrogen, white).

The propionic acid groups attached to the inner two pyrrole rings of the bilirubin molecule are the site of conjugation with glucuronic acid. The mono- and diglucuronides of bilirubin so formed retain the more open, water-soluble conformation by reducing or preventing intramolecular hydrogen bonding. Polar groupings remain similarly exposed in the naturally occurring β and δ isomers of bilirubin and in the isomers produced by phototherapy, enabling them to be freely excreted in bile (Ennever 1992).

Bilirubin metabolism and excretion

In the newborn baby bilirubin arises mainly from the breakdown of red cells, with up to a quarter resulting from ineffective erythropoiesis and other haem-containing compounds, such as myoglobin and cytochromes. Bilirubin is transported in the blood bound reversibly to serum albumin on high- and low-affinity sites, with a potential molar bilirubin to albumin ratio up to 3:1. Under normal circumstances, the proportion of free bilirubin circulating in the jaundiced newborn is very low (<5 nmol/l).

Conjugation of bilirubin with glucuronic acid occurs in the smooth endoplasmic reticulum to form water-soluble mono- and diglucuronides of bilirubin. These reactions are catalysed by the microsomal enzyme hepatic uridine diphosphoglucuronosyl transferase (UDPGT). Conjugated bilirubin (chiefly the monoglucuronide in the newborn) is actively transported out of the liver cell and enters the biliary canaliculi as a component of bile.

In adults, most of the conjugated bilirubin is converted by colonic flora to urobilinogen before elimination in the stool. In the newborn, a significant proportion is hydrolysed by β -glucuronidase in the small gut to yield unconjugated bilirubin, which can re-enter the circulating pool via the enterohepatic circulation.

Biochemical basis of phototherapy

Phototherapy detoxifies bilirubin and facilitates its excretion from the body via routes other than conjugation in the liver (McDonagh and Lightner 1985; Ennever 1992). When bilirubin interacts with a photon of light, three photochemical reactions can occur. They are photo-oxidation, configurational isomerisation and structural isomerisation. Photo-oxidation causes disruption of the bilirubin molecule to form colourless polar fragments that are readily excreted in urine. Although this process reminds us of the need to avoid exposure of serum samples to direct sunlight (Cremer et al. 1958), it plays only a minor role in bilirubin excretion during phototherapy.

Configurational isomerisation results from molecular reorientation around the double bonds between carbon atoms 4–5 and 15–16 (Fig. 29.2). In the natural form, the arrangement of these double bonds, and hence the alignment of the end pyrrole rings, is classified as bilirubin-4Z,15Z (Z = *zusammen*, together). A photon of light striking the bilirubin molecule can temporarily disrupt the double bonds and initiate a 180° rotation of one or both end pyrrole rings to produce three isomeric forms, designated: 4Z,15E; 4E,15Z; and 4E,15E (E = *entgegen*, apart).

Formation of bilirubin-Z,E is favoured during phototherapy and its conformation (as shown in Fig. 29.4) maintains exposure of polar groups at one end of the molecule, facilitating its excretion, unconjugated, in bile. Whilst bound to albumin, the configurational isomers remain stable for a number of hours. Once in bile, a rapid deconfiguration occurs, and unconjugated bilirubin-Z,Z entering the gut is available for reuptake into the bloodstream via the enterohepatic circulation.

Fig. 29.4 Configurational photoisomerisation of bilirubin.

Fig. 29.5 Structural photoisomerisation of bilirubin to form lumirubin.

It was originally thought that phototherapy acted mainly through configurational isomerisation. Although rapidly produced, these isomers are slowly cleared in humans. The serum half-life of bilirubin-Z,E is about 15 hours, and after some 6–12 hours of phototherapy a steady state is achieved with approximately 20% of the total serum bilirubin in the form of the configurational isomers. Importantly, this is likely to mean that up to one-fifth of the circulating bilirubin is detoxified, despite not being in a form that is readily excreted. This fraction may reach one-quarter in combination with other isomers mentioned below.

The main contributor to bilirubin excretion during phototherapy is thought to be the formation of the structural isomer lumirubin, which is formed by 'cyclisation' of one end of the bilirubin molecule, as shown in Figure 29.5. This structural change is irreversible and allows the more polar product to be excreted in bile and urine. More efficient elimination is reflected by lumirubin's half-life of less than 2 hours and steady-state level during phototherapy of 2–6% of the total serum bilirubin. Unlike the configurational isomer, production of lumirubin follows a dose–response relationship with the irradiance of phototherapy applied. Its production is favoured by the use of light of a longer wavelength than that of conventional phototherapy, but there are few advocates for the use of green lights.

The normal pattern of neonatal jaundice

The fetus excretes unconjugated bilirubin via the placenta and maternal liver. In the absence of fetal hyperbilirubinaemia or maternal liver disease, the mean bilirubin level in umbilical cord blood at birth is 20–35 $\mu\text{mol/l}$ (Knudsen and Lebech 1989). Most newborn babies have an increase in serum bilirubin in the first week of life, reaching clinically detectable levels in about 60% of term

Table 29.1 Factors that exacerbate jaundice in the newborn

Polycythaemia
Delayed cord clamping
Maternofetal transfusion
Recipient of twin–twin transfusion
Extravasated blood
Bruising (e.g. cephalhaematoma)
Birth trauma
Internal haemorrhage
Delayed passage of meconium
Swallowed blood
Hypocaloric feed intake
Dehydration
Breastfeeding
Prematurity

and 80% of preterm infants. This has been referred to as physiological jaundice. In healthy term formula-fed babies, the serum bilirubin peaks on the third to fourth day of life, becoming clinically detectable at levels above 80 $\mu\text{mol/l}$. Following this phase I peak, serum bilirubin levels fall rapidly for 2–3 days and then more gradually, reaching normal adult values between 1 and 2 weeks of age (phase II). Exclusively breastfed babies often have a delayed serum bilirubin peak and a more prolonged course to their jaundice. This pattern of jaundice is the result of increased bilirubin production at a time when the mechanisms for liver uptake, transport and conjugation of bilirubin are immature. At higher serum bilirubin levels, the excretion of bilirubin into bile may be rate-limiting. The biphasic pattern of normal neonatal jaundice results from a deficiency of UDPGT activity in the first phase and low intrahepatic binding protein levels in the second.

The pattern of neonatal jaundice in prematurely born babies is characterised by a higher peak serum bilirubin level, occurring on days 5–7, and a longer phase II, persisting for 2–4 weeks. This potential for heightened jaundice also applies to the late preterm infant (gestational age 34⁺⁰–36⁺⁶ weeks). Bilirubin production during the first weeks of life is more than double that of the adult. This excess bilirubin load in the newborn results from factors that include a higher haematocrit, increased red cell turnover and a greater contribution from sources of haem other than senescent erythrocytes. In addition, the 10-fold higher level of β -glucuronidase in the small bowel brush border of the newborn reverses the conjugation process, liberating more unconjugated bilirubin to join the enterohepatic circulation. Other risk factors that exacerbate neonatal jaundice are listed in Table 29.1. It must be appreciated that in such circumstances, and despite the lack of an underlying pathology, the serum bilirubin may attain levels causal of transient auditory derangement (Tan et al. 1992) or permanent neurological damage (Maisels and Newman 1995). For this reason the confusing old terms 'physiological' and 'pathological jaundice' are best avoided (Maisels 2006).

Epidemiology and genetics

Developments in human genomics are providing explanations for the epidemiological variation in neonatal hyperbilirubinaemia and susceptibility to bilirubin encephalopathy (Watchko et al. 2002). Gilbert syndrome is a contributory factor in some pronounced and prolonged unconjugated jaundice (Monaghan 1999). A variant in the promoter for the gene encoding UDPGT results in

a reduction of the enzyme's activity by as much as two-thirds. The syndrome is common, affecting 5–10% of the population in the homozygous state. The heterozygous Gilbert's state, present in 42% of the population, has also been shown to contribute to hyperbilirubinaemia (Kadakol et al. 2001). A combination of Gilbert syndrome and glucose-6-phosphate dehydrogenase (G6PD) deficiency has been responsible for severe cases of hyperbilirubinaemia (Kaplan 2001).

In babies with pathology underlying their jaundice blood group incompatibility, G6PD deficiency and infection are the conditions most commonly associated with significant hyperbilirubinaemia and kernicterus. They vary in prevalence in different parts of the world, as reflected in the meta-analysis conducted as part of a literature review for the UK National Institute for Health and Clinical Excellence (NICE) guideline on neonatal jaundice (National Institute for Health and Clinical Excellence 2010). In Africa G6PD deficiency accounted for over 35% of cases of significant hyperbilirubinaemia and kernicterus, and for infection this figure was more than 14%. In the Middle East, infection was found in 50% of cases of kernicterus. In Europe and North America G6PD deficiency was implicated in 5% of babies with a serum bilirubin >400 $\mu\text{mol/l}$ or receiving exchange transfusions, and 20% of cases of kernicterus. Infection was implicated in 2% of babies with a serum bilirubin >400 $\mu\text{mol/l}$ or receiving exchange transfusions, and in 14% of cases of kernicterus. Among jaundiced babies in Europe and North America blood group incompatibility was the most prevalent underlying factor leading to higher bilirubin levels (>400 $\mu\text{mol/l}$), whereas G6PD deficiency was more common in cases of kernicterus. In all geographical settings no cause is ever found for significant hyperbilirubinaemia in an appreciable percentage of cases.

Jaundice in the healthy breastfed infant

Breastfed babies develop more marked and prolonged jaundice than those who are formula-fed. The peak bilirubin level in the formula-fed infant usually occurs on day 3 or 4, whereas in the breastfed baby it may not be reached until the end of the first week or entering the second week of life. This influence of exclusive breastfeeding is also seen in babies born prematurely (Lucas and Baker 1986). The neonatal jaundice commonly seen in the breastfed baby during the first week of life relates to lower calorie intake, and the slower passage of meconium. When associated with marked weight loss, this pattern of jaundice in the breastfed newborn has been referred to as 'lack-of-breast-milk jaundice' (Hansen 1995).

Up to one-third of breastfed babies remain clinically jaundiced beyond 2 weeks of age, and they represent the overwhelming majority of infants presenting for a prolonged jaundice screen. A reliable diagnosis of breast milk jaundice can only be made on exclusion of pathological causes. Once the diagnosis is made, parents should be warned that resolution of jaundice might take several weeks. They should be advised to report back if the nature of the jaundice changes, there is failure to thrive or their baby develops pale chalky stools and dark urine. Although interruption of breast milk feeds and supplementation with formula for 24 hours may be associated with a marked decline in serum bilirubin and lower rebound level on reintroduction, the practice is rarely justified. Also to be discouraged is the vogue for supplementing breastfed infants with water, regardless of their state of hydration. Newborns managed in this way have been shown to have higher maximum serum bilirubin levels (De Carvalho et al. 1981).

The prolonged form of jaundice seen in the breastfed baby beyond the second week of life is thought to be related to enhanced

enterohepatic circulation of bilirubin. The presence in breast milk of β -glucuronidase – which unconjugates bilirubin in the infant gut, enabling it to re-enter the circulation – is thought to be contributory. Altered bacterial colonisation of the gut in the breastfed baby with a resultant decrease in the conversion of bilirubin glucuronides to urobilinoids may also play a role.

Pathophysiology of bilirubin encephalopathy

Kernicterus

Kernicterus is the name given to the characteristic pattern of yellow staining of parts of the brainstem, hippocampus, cerebellum and certain brainstem nuclei (particularly the globus pallidus and subthalamic nucleus) seen at autopsy in infants dying with acute bilirubin toxicity (Fig. 29.6). The clinical manifestations of bilirubin encephalopathy arise from the susceptibility to damage of the basal ganglia, brainstem auditory pathways and oculomotor nuclei (Volpe 2008; Shapiro 2010). This anatomical preference for bilirubin deposition and vulnerability to toxicity has not been fully explained, but may be a consequence of increased blood flow and metabolic activity in these areas (Burgess et al. 1985). Regional variation in bilirubin influx, detoxification and clearance and the variance in neuronal cell inflammatory response are also likely to be implicated (Brites et al. 2009).

The blood–brain barrier is anatomically derived from tight junctions between the endothelial cells of cerebral blood vessels. This barrier remains permeable to lipid-soluble substances, but, whilst intact, excludes water-soluble substances and large molecules, such as proteins. Free bilirubin influxes and effluxes across the intact blood–brain barrier. Disruption of the blood–brain barrier will allow an influx of albumin-bound bilirubin as well as free bilirubin into the brain, and the distribution of bilirubin staining may suggest kernicterus. There was a lack of correlation between bilirubin staining and histological evidence of neuronal injury observed in the brains of premature infants dying from other causes in the so-called low-bilirubin kernicterus era (Turkel et al. 1982).

Fig. 29.6 Macroscopic appearance of brain in a term infant with kernicterus.

Bilirubin toxicity

Bilirubin's toxicity is that of a generalised cellular poison. Disruption of membrane function, lowering of action potentials, compromise of energy metabolism and disturbance of neurotransmitter synthesis and neurotransmission are some of the mechanisms implicated (Volpe 2008; Brites et al. 2009). Advances in human genomics are identifying factors that predispose to hyperbilirubinaemia and bilirubin encephalopathy (Kaplan et al. 2003). There is evidence that bilirubin is a substrate for P-glycoprotein, a plasma membrane efflux pump found on the luminal surface of brain capillary endothelial cells and considered responsible for limiting entry of certain lipophilic substrates into the central nervous system (Watchko et al. 2002; Wennberg et al. 2006). P-glycoprotein function may be inhibited by drugs. Its expression is also related to gestational maturity, and this may be a factor contributing to the greater vulnerability of the premature brain to bilirubin neurotoxicity. Also implicated is the maturational state of nerve cells exposed to bilirubin, with a greater tendency to apoptosis seen in the less well-differentiated astrocytes and neurons (Brites et al. 2009).

Attempts to reproduce bilirubin neurotoxicity experimentally point to the importance of coexisting risk factors, such as acidosis, hypoxia, hypercarbia and blood–brain barrier disruption, as being prerequisites for bilirubin's toxicity (Wennberg et al. 2006). Hypercarbia should not be underestimated as a risk factor, through disruption of the blood–brain barrier.

Agents that interfere with the binding of bilirubin to serum albumin may also promote neurotoxicity. The devastating effect in the 1960s of sulphisoxazole causing kernicterus (Silverman et al. 1956) serves as a reminder that all drugs used in neonatology should be assessed in terms of their potential to displace bilirubin from albumin (Robertson et al. 1991). Free fatty acids, if they reach a molar ratio with albumin in excess of 4:1, interfere with bilirubin binding. Such ratios may be attained in sick immature newborns receiving high-dose intravenous lipid preparations.

Insight into bilirubin encephalopathy can be gained from case reports of infants who experience very high levels of bilirubin but escape neurological sequelae. Hanko et al. (2001) describe a baby with ABO incompatibility developing a peak serum bilirubin of 636 $\mu\text{mol/l}$ at 19 hours of age who made normal progress after the bilirubin level was reduced to <400 $\mu\text{mol/l}$ by 35 hours of age. By contrast, the authors report two babies who went on to develop kernicterus from jaundice peaking at 650 and 717 $\mu\text{mol/l}$, and in whom the bilirubin was not reduced to <400 $\mu\text{mol/l}$ until 60 and 68 hours. It is suggested that it may be the duration of significant hyperbilirubinaemia or 'area under the curve' that is as important in neurotoxicity. This factor has been implicated in a number of the cases studied from the Pilot USA Kernicterus Registry for term and near-term infants, as has the rate of rise in serum bilirubin (Johnson et al. 2009).

Other factors influence the passage of bilirubin into the brain and hence increase the risk of acute bilirubin encephalopathy. These include sepsis, hypoxia, seizures, hypercarbia, acidosis and hypoalbuminaemia. A healthy term baby with none of these risk factors is most unlikely to develop kernicterus below a serum bilirubin concentration of 425 $\mu\text{mol/l}$, but that risk increases significantly at bilirubin levels in excess of 515 $\mu\text{mol/l}$ (Manning et al. 2007; Johnson et al. 2009).

Clinical bilirubin encephalopathy

The word 'kernicterus' originates from a description of yellow nuclear staining of the brain, but has become synonymous with the acute and chronic neurological features of what are more correctly

termed bilirubin encephalopathy and its sequelae. Descriptions of classic kernicterus arise from observations of markedly jaundiced infants with erythroblastosis fetalis before the advent of effective phototherapy and exchange transfusion. At that time three clinical phases were identified (Connolly and Volpe 1990; Volpe 2008). The first few days were characterised by lethargy, hypotonia and poor suck. Towards the end of the first week, a second phase was heralded by hypertonia, often with opisthotonus. At this stage, the baby commonly exhibited a high-pitched cry, fever and seizures. The third phase was entered as the hypertonia subsided, to be replaced by hypotonia. Current-day intervention during phase 1 with feeding support, phototherapy and, if necessary, exchange transfusion can prevent evolution of long-term damage. The onset of hypertonia and opisthotonus, often coincident with peak serum bilirubin level, remain poor prognostic signs predictive of neurological sequelae. The preterm infant may exhibit little in the way of acute signs in the neonatal period, yet may go on to develop clinical kernicterus. Isolated sensorineural hearing loss may become apparent in both term and preterm infants exposed to significant hyperbilirubinaemia. Dental enamel dysplasia may be another consequence of levels of bilirubin that result in kernicterus.

The long-term features of bilirubin encephalopathy include extrapyramidal disturbances, auditory impairment and upward-gaze palsies. The resulting cerebral palsy typically has an element of athetosis, which can develop as early as 18 months of age or be delayed for several years. High-frequency sensorineural deafness frequently accompanies the cerebral palsy, but may evolve in isolation. Cognitive impairment can result from bilirubin encephalopathy, but is commonly absent. A characteristic brain magnetic resonance imaging (MRI) pattern has been described in cases of kernicterus. The presence of high-intensity areas in the posteromedial border of the globus pallidus on T_2 -weighted imaging is considered the most sensitive finding (Yokochi 1995; Govaert et al. 2003). Kernicteric brain MRI changes are illustrated in Figure 29.7. It should be appreciated that chronic neurological features of clinical kernicterus can be seen in the absence of any abnormality on brain MRI (Katar et al. 2008).

Lessons from the past and present

The 'kinder, gentler approach' towards the healthy jaundiced term infant

Up until the last two decades, treatment thresholds for phototherapy and exchange transfusion tended to reflect clinical experience gained by early exponents of exchange transfusion in severe erythroblastosis fetalis. They determined that kernicterus was unlikely to occur if serum bilirubin levels were kept below 20 mg/dl (342 μ mol/l). The impact was such that an 'irrational fear of 20 mg/dl' or 'vigintiphobia' (Watchko and Oski 1983) led to adoption of this exchange threshold for all infants, regardless of the cause of jaundice or their gestation. A campaign for 'a kinder, gentler approach' to the treatment of jaundice in healthy, non-haemolysing term infants was started by Newman and Maisels (1992), who carried out an extensive review of the existing literature before proposing their less interventional management regimens. It remains uncertain as to whether there are significant or long-term effects of moderate hyperbilirubinaemia (Maisels and Newman 2001).

Premature infants

Premature infants are more prone to bilirubin encephalopathy than their full-term counterparts. The greater risk to the preterm brain may have been overstated in the past following incorrect

Fig. 29.7 T_2 -weighted axial section of the brain imaged with magnetic resonance imaging, showing characteristic changes of kernicterus in the globus pallidus (arrowed).

Fig. 29.8 Macroscopic appearance of brain in an extremely low-birthweight infant with low-bilirubin 'kernicterus'.

interpretation of autopsy findings in the so-called 'low-bilirubin kernicterus era' (1965–82). This was a time when all yellow staining of the basal ganglia merited the description kernicterus, regardless of histological confirmation. Agonal changes in blood–brain barrier permeability to albumin-bound as well as free bilirubin in infants dying from other causes have been implicated in this pattern of staining (Fig. 29.8). This is not to be confused with our more recent

understanding of kernicterus occurring in extreme preterm infants at low pretreatment threshold bilirubin levels, as demonstrated on brain MRI (Govaert et al. 2003).

Elevated serum bilirubin levels appear in some studies to be a risk factor for hearing loss in premature babies. The high incidence of bilateral sensorineural deafness in a population of sick very-low-birthweight infants with serum bilirubin levels $>240 \mu\text{mol/l}$ was dramatically reduced when lower thresholds for intervention were adopted (DeVries et al. 1985, 1987). Deafness in this population was also shown to correlate with the mean duration of hyperbilirubinaemia.

There have been calls for relaxation of the more interventional treatment regimens applied to the jaundiced preterm population (Watchko and Oski 1992), and counterarguments raised against (Ives 1992). The proponents based their argument on experience gained in a pre-intensive care era (1950–65) with relatively more mature (28–36 weeks' gestation) infants, very few of whom were exposed to serum bilirubin levels in excess of $340 \mu\text{mol/l}$. False reassurance was also gained from trials conducted against the backdrop of the recent more interventionalist therapeutic regimens. The large National Institute of Child Health and Human Development phototherapy trial failed to demonstrate an association between maximal serum bilirubin level and neurodevelopmental outcome in term or preterm infants (Scheidt et al. 1991), but threshold criteria used for exchange transfusion had kept serum bilirubin levels low. The pre-emptive treatment of jaundice with phototherapy in low-birthweight infants has reduced dramatically the requirement for exchange transfusion, but we remain uncertain as to the appropriate thresholds for treatment (Maisels and Watchko 2003; Morris et al. 2008; Watchko and Maisels 2010).

Lessons from reports of babies with kernicterus

What is the evidence that an otherwise healthy, non-haemolysing term baby can develop kernicterus? Six cases have been reported in which apparent 'exaggerated physiological jaundice' was associated with signs of acute bilirubin encephalopathy and typical neurological sequelae (Maisels and Newman 1995). Peak recorded bilirubin levels with a range of $663\text{--}845 \mu\text{mol/l}$ occurred between days 4 and 10. Four of the babies were 37 weeks' gestation and four had significant weight loss. The largest proportion of babies reported to the Pilot USA Kernicterus Registry has idiopathic jaundice.

A prospective 2-year surveillance study of hyperbilirubinaemia (unconjugated serum bilirubin $>510 \mu\text{mol/l}$ in the first month of life) in the UK and Ireland has highlighted the prevalence and risk to the baby of such levels of jaundice (Manning et al. 2007). The mean peak serum bilirubin level was 580 (range $510\text{--}802$) $\mu\text{mol/l}$, and the mean gestational age was 38.2 (range $35\text{--}42$) weeks. The 108 patients identified provide an incidence of this level of jaundice of $7.1/100\,000$ live births. Of this group, 14 (13%) had features consistent with acute bilirubin encephalopathy. From this study the UK incidence of acute bilirubin encephalopathy was $0.9/100\,000$ live births, although not all affected babies went on to develop chronic kernicterus. It should also be noted that this surveillance study did not take into account the more preterm population, cases of bilirubin encephalopathy that may have occurred at lower serum bilirubin levels and instances of kernicterus where there was a high conjugated component to the jaundice but the unconjugated value did not exceed $510 \mu\text{mol/l}$. As in the case reports mentioned above (Maisels and Newman 1995), failure to establish breastfeeding ('lack-of-breast-milk jaundice') and being born near term featured amongst the patients. The pitfall of treating late preterm infants as healthy term infants has been emphasised (Bhutani and Johnson 2006). There were also similarities between the affected patient

profile in this UK and Ireland survey and the USA-based Kernicterus Registry (Johnson et al. 2009) in terms of breastfeeding predominance, darker skin tones that may mask jaundice and G6PD deficiency.

The Pilot USA Kernicterus Registry

As long as kernicterus continues to occur, better understanding of the circumstances leading to individual cases and a collective strategy of prevention will best be achieved by maintaining national registries. A pilot kernicterus registry for term and near-term infants was established in the USA in 1992 (Bhutani and Johnson 2009a; Johnson et al. 2009). The level of case ascertainment and state coverage of this registry does not allow the authors to generate information on the national incidence of kernicterus, but they are able to derive important clinical lessons. Haemolysis (19%) and G6PD deficiency (22%) feature highly as underlying causes, whilst other pathologies (23%) and idiopathic cases (36%) make up the remainder. Lactation failure with suboptimal lactation support was a feature in more than 90% of the infants who had been discharged home exclusively breastfeeding. No specific serum bilirubin threshold emerges as the trigger for bilirubin encephalopathy, but a narrow margin of safety appears to exist between levels of 425 and $595 \mu\text{mol/l}$. Kernicterus stands out as a preventable disorder in the majority of cases reported in the registry.

The case emerges for a 'crash-cart' approach to commencing multiple phototherapy and securing blood for an urgent exchange transfusion for babies presenting with significant hyperbilirubinaemia or symptomatic bilirubin encephalopathy. Of babies managed in this manner, 73% avoided chronic sequelae. The latest report from the registry concludes: 'The major underlying root cause for kernicterus was systems failure of services by multiple providers at multiple sites and inability to identify the at-risk infant and manage severe hyperbilirubinaemia in a timely manner' (Johnson et al. 2009).

Identifying the newborn at risk of bilirubin encephalopathy

Predischarge prediction of the severity of jaundice

In the context of early postnatal discharge and a varying degree of community support, American authors have turned to a predischarge serum bilirubin estimation in an attempt to categorise the risk of subsequent significant hyperbilirubinaemia based on an hour-specific bilirubin nomogram (Bhutani et al. 1999). The nomogram was generated from measurements of total serum bilirubin in 2840 term and near-term infants eligible for discharge between 24 and 72 hours of age. The predischarge bilirubin assay was performed with the routine metabolic screen at a mean age of 33.7 ± 14.6 SD hours. Postdischarge values were obtained to determine whether the initial measurement was predictive of the natural history of jaundice. Just over 60% of the study population fell into a low-risk category and did not progress to significant jaundice. The remaining patients were in risk zones that were either high risk or they had the potential to move to the high-risk zone from an intermediate-risk zone. If applying the nomogram to other populations of newborn infants it should be remembered that this was a selected group that excluded many first-day discharges, babies with evidence of rhesus or ABO sensitisation, babies admitted to a special care baby unit/neonatal intensive care unit, and newborns who required phototherapy before the age of 60 hours for a rapidly

rising serum bilirubin. A recent study has shown that an assessment that combines timed transcutaneous bilirubin levels above the 95th percentile on the Bhutani nomogram with risk factors for significant hyperbilirubinaemia is effective at preventing later significant hyperbilirubinaemia (Maisels et al. 2009a).

New UK national guidelines

Recent national guidance in the UK has emphasised review within 48 hours of birth of babies with known risk factors for significant hyperbilirubinaemia, and recommends measurement as opposed to estimating the bilirubin level in all babies presenting with clinical jaundice (National Institute for Health and Clinical Excellence 2010). The NICE guideline on neonatal jaundice aims to improve recognition of infants who have an increased risk of developing significant jaundice. Studies show that four factors are independently associated with an increased risk of hyperbilirubinaemia (Khoury et al. 1988; Newman et al. 2002; Keren et al. 2005; Maisels et al. 2009a). They are: (1) gestational age <38 weeks; (2) jaundice within 24 hours of life; (3) mother's intention to breastfeed exclusively; and (4) a family history of neonatal jaundice. The UK NICE guideline has used these four risk factors to highlight babies at risk of significant hyperbilirubinaemia (that is, requiring treatment) and to promote their earlier surveillance, and produced a care pathway (Fig. 29.9). Factors such as bruising, cephalhaematoma, vacuum delivery, male sex and race were not added to this risk assessment as studies have not shown a consistent causal association between them and hyperbilirubinaemia.

Risk factors in babies more likely to develop significant hyperbilirubinaemia include:

- gestational age under 38 weeks
- a previous sibling with neonatal jaundice requiring phototherapy
- mother's intention to breastfeed exclusively
- visible jaundice in the first 24 hours of life

For babies with any or all of the four risk factors, an additional clinical examination for clinical jaundice is to be conducted in the period up to 48 hours of age.

Clinical jaundice is more difficult to recognise in babies with dark skin tones and can be missed without close examination of the sclerae, gums and blanched skin. This explains why kernicterus registries (Johnson et al. 2009) and population studies of hyperbilirubinaemia (Manning et al. 2007) report overrepresentation of babies from ethnic groups with dark skin tones. These babies fall into the heightened risk group if they are not examined properly. In cases of doubt, a low threshold should be adopted for checking the transcutaneous or serum bilirubin.

Markers of bilirubin toxicity

The imprecise relationship between total serum bilirubin levels and adverse neurological outcome has encouraged research seeking to identify more accurate markers of bilirubin toxicity. Assessments of free bilirubin levels, bilirubin-binding capacity and brainstem auditory evoked responses have been proposed (Funato et al. 1994). These markers may prove of value in research environments, but they are not universally available in the acute clinical situation. Clinicians have traditionally focused on the total serum bilirubin as the arbiter of treatment thresholds for jaundice. An assay of free bilirubin may be the more relevant marker (Wennberg et al. 2006). Correlation of abnormal auditory brainstem responses in infants of 28–32 weeks' gestation has been demonstrated with peak free bilirubin level but not the total bilirubin value in a range of moderate jaundice (Amin et al. 2001).

More accessible than free bilirubin measurement is the bilirubin/albumin ratio, which is related indirectly to the free bilirubin level. The bilirubin/albumin ratio has also been shown to correlate with abnormal auditory brainstem responses when the total bilirubin failed to do so (Amin et al. 2001). On the basis of unbound bilirubin estimations, an exchange transfusion threshold has been proposed at a bilirubin/albumin ratio of 0.8 in the healthy term newborn, 0.72 in a sick term infant and as low as 0.4 for the sick premature infant of <1250 g (Ahlfors 1994). Although this ratio has not gained widespread clinical acceptance, it may help to inform the decision as to whether or not to perform an exchange transfusion in borderline cases (AAP 2004; Maisels et al. 2009b). (Note that, when calculating the bilirubin/albumin ratio, values for serum albumin concentration in g/l should be converted to SI units of $\mu\text{mol/l}$ using the factor 15.15.)

A systematic review has examined the usefulness of the bilirubin/albumin ratio for predicting bilirubin-induced neurotoxicity in premature infants (Hulzebos et al. 2008). The authors identified six studies that suggest that there is a link between the bilirubin/albumin ratio and various indices of bilirubin encephalopathy, including abnormal auditory brainstem responses. The same authors are due to publish the results of a randomised controlled trial (Bilirubin Albumin Ratio Trial (BARtrial), <http://www.controlled-trials.com/isrctn/pf/74465643>) which has looked at the use of the bilirubin/albumin ratio as an adjunct to decision-making on thresholds for phototherapy and exchange transfusion in preterm infants born at less than 32 weeks' gestation. Neurodevelopmental outcome is being assessed at 18–24 months of age.

Assessing the level of serum bilirubin

Visual inspection

Clinical jaundice becomes visually apparent at serum bilirubin levels of 80–90 $\mu\text{mol/l}$, and can be observed in the majority of newborns during the first week of life. Examination for jaundice should be conducted in a well-lit room. Jaundice may be more difficult to detect in preterm infants and missed in babies with darker skin tones, in whom examination of the sclerae, gums and blanched skin may be more informative. Visual assessment can be unreliable under artificial light, and once phototherapy has been commenced. Healthcare professionals and parents can be taught to recognise clinical jaundice, but studies show that they are unable to assess its severity. Accuracy is not enhanced by the use of icterometers or assessment of the cephalocaudal progression of dermal jaundice (Kramer 1969). For these reasons, whenever a parent or healthcare professional considers that a baby is visibly jaundiced, the bilirubin level must be measured to inform appropriate clinical management and the timing of repeat assessment.

Transcutaneous bilirubinometry

Over the past decade the use of non-invasive transcutaneous bilirubinometry has become well established in the USA and is currently entering UK practice. Transcutaneous bilirubin measurement has evolved to a range of accuracy that it can be used with confidence in the assessment of the degree of jaundice up to levels of 250 $\mu\text{mol/l}$ in babies of 35 weeks' gestation and above. Machines available in the UK are the Minolta JM-103 (Konica Minolta/Air-Shields) and the BiliChek (Respironics). They have been subjected to numerous trials but there are currently no published studies directly comparing the two.

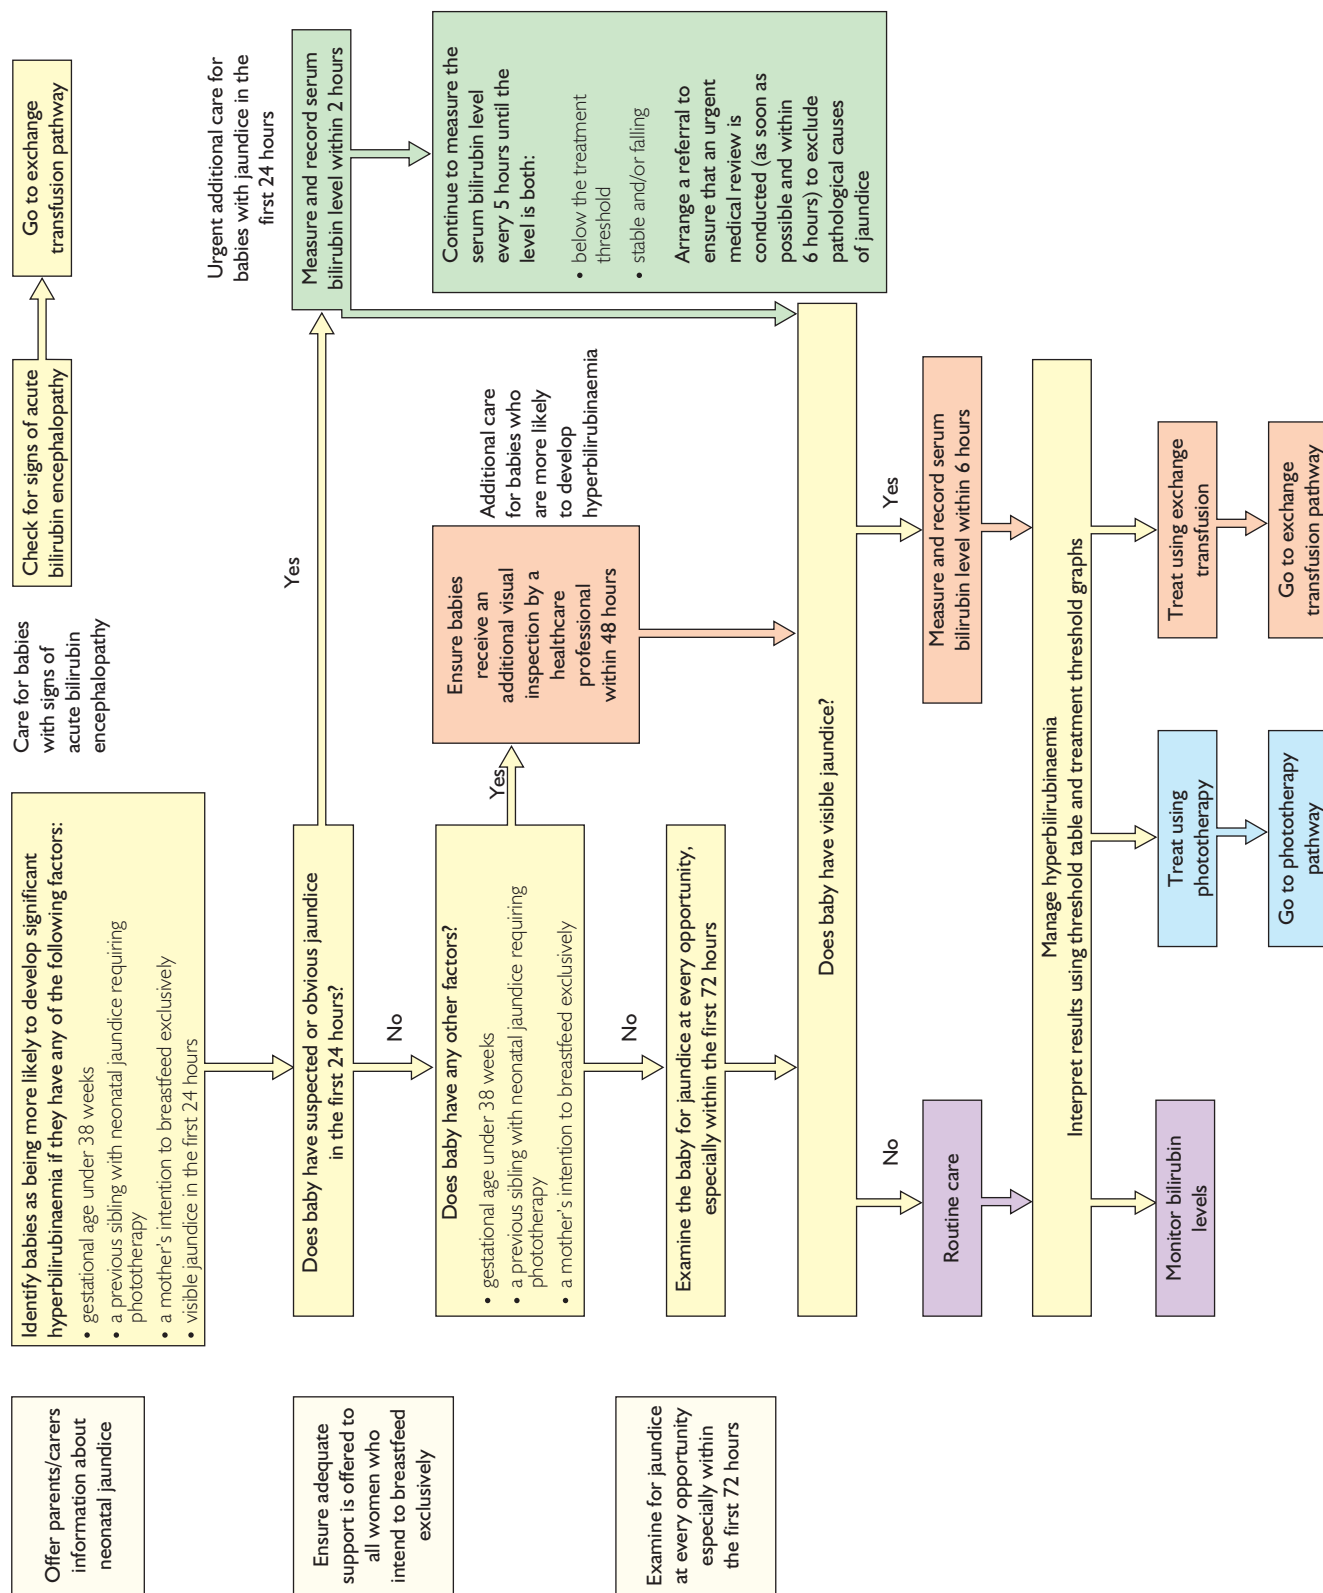

Fig. 29.9 National Institute for Health and Clinical Excellence investigation pathways.

These devices measure yellow pigments including bilirubin in blanched skin by sampling from the forehead or anterior chest wall over the sternum. They provide a significant positive correlation with serum bilirubin levels in moderately jaundiced infants and reduce the requirement for blood sampling. The difference between transcutaneous bilirubin and serum bilirubin widens at levels above 250 $\mu\text{mol/l}$, and validation of the accuracy of transcutaneous bilirubinometry in preterm babies born at <35 weeks' gestation is limited. The current UK NICE guidance recommends that, if a transcutaneous bilirubinometer records a bilirubin level above 250 $\mu\text{mol/l}$, a serum sample should be taken to check the bilirubin level more accurately. Phototherapy, through its bleaching effect on the skin, precludes the use of transcutaneous bilirubinometry to monitor the progress of treatment once phototherapy is in progress.

Invasive blood sampling

For practical purposes, a bench bilirubinometer employing direct spectrometry is used in many neonatal units to provide near-patient estimation of total serum bilirubin. It should be remembered that such instruments reflect the sum value of all species of bilirubin, conjugated and unconjugated, including photoisomers. Significant errors can arise from incorrect spectrometer use and poor maintenance. Failure by the operator to note that serum specimens are grossly lipaemic, or that the outside of the capillary tube or cuvette is dirty, will give misleading results. Regular instrument quality control and calibration are necessary. The bilirubinometer used should be accurate to within $\pm 20\text{--}30\text{ }\mu\text{mol/l}$, and the limitations of the machine should be known when measuring very high values. Whole-blood bilirubin assay is available on some modern blood gas analysers and may be used as an alternative. If near-patient testing is unavailable a laboratory service must be in place with a reliable and timely method of communicating results back to the nursery. It is customary to confirm pre-exchange transfusion values of total serum bilirubin with a laboratory measurement, but the procedure should not be delayed if this service is slow.

There are no clear-cut levels of total serum bilirubin that predict the risk of bilirubin encephalopathy and this has encouraged research into the measurement of free bilirubin, unbound to albumin (Wennberg et al. 2006). After several hours of phototherapy as much as 25% of the circulating unconjugated bilirubin pool may be in the form of isomers. These are probably measured within the total value for most serum bilirubin assays but may hinder the precision of attempts to use the free bilirubin level to guide management of jaundice (McDonagh 2006).

Identifying different types of jaundice

Jaundice with a pathological cause

Every jaundiced infant should be clinically evaluated to identify underlying pathology and to assess the risk potential for bilirubin encephalopathy. Family, maternal and infant history should be reviewed and the baby examined. Appropriate early investigation aims to identify treatable disease states, such as isoimmunisation (most commonly rhesus or ABO incompatibility), infection, hypothyroidism, biliary atresia and galactosaemia. Clinical features that suggest a pathological cause of jaundice and prompt further investigation are listed in Table 29.2. Many of the more commonly recognised causes of unconjugated hyperbilirubinaemia are listed in Table 29.3. Unless there are diagnostic pointers to the more rarely

Table 29.2 Clinical features that suggest a pathological cause of jaundice in the newborn

encountered causes of neonatal jaundice, stepwise investigation should aim to identify the common ones first (Table 29.4).

Defining the severity of jaundice

The ambiguity of the redundant terms 'physiological' and 'pathological jaundice' has been matched by attempts to describe and define the severity of jaundice. There is no consensus as to the meaning of hyperbilirubinaemia, or versions thereof with various adjectives attached. Levels of bilirubin $>510 \mu\text{mol/l}$ have been described recently as 'severe', 'extreme', 'hazardous' or 'catastrophic' hyperbilirubinaemia by different authors (Bhutani et al. 1999; Maisels 2006; Manning et al. 2007; Bhutani and Johnson 2009b). If we are destined to categorise levels of jaundice, numerical ranges should suffice. The simplest use of terminology is to use 'hyperbilirubinaemia' to denote a raised level of bilirubin in the blood, 'clinical jaundice' to mean visually detectable jaundice and 'significant hyperbilirubinaemia' to describe a level of jaundice requiring treatment. Regardless of the level, jaundice in the first 24 hours of life and rates of rise in serum bilirubin consistent with haemolysis take on their own significance.

Early-onset jaundice

Jaundice within the first 24 hours of life is likely to be the result of isoimmunisation or other cause of significant haemolysis. In the absence of haemolysis, the rare Crigler–Najjar syndromes should be considered. Urgent investigation is essential (Table 29.4). Maternal rhesus status and blood group should be sought. Infants of known rhesus-negative mothers may have had cord or postnatal blood sent for a direct antiglobulin test (DAT). Antenatal anti-D prophylaxis in rhesus-negative women can result in passive transfer of antibody, resulting in a weakly positive DAT in the absence of haemolysis (Maayan-Metzger et al. 2001). Routine DAT testing on umbilical cord blood of all babies has not been shown to predict subsequent hyperbilirubinaemia accurately in the newborn. Despite

an ABO incompatibility set-up in 10–15% of pregnancies, the number of cases that result in significant haemolysis is small. The finding of a positive DAT is not predictive of the severity of jaundice, and nor does a negative result rule out the condition. Maternal anti-A or anti-B immunoglobulin G titre greater than 1 in 512 is likely to be associated with significant hyperbilirubinaemia (Bakkeheim et al. 2009).

Other blood group incompatibilities will usually be known from the maternal history. The Kell group can cause severe haemolytic disease of the newborn, whereas complications of the Duffy, Kidd and other rare blood group systems are usually less severe. A reticulocyte count of more than 6% after 3 days is suggestive of a haemolytic process, but reticulocyte counts and blood films carry a low sensitivity and specificity for diagnosing haemolysis in the newborn (Newman and Easterling 1994). Screening for G6PD deficiency should be considered in babies of relevant ethnic origin, although this condition more usually presents from day 3 onwards. Carbon monoxide is produced in equimolar quantities with bilirubin during haem catabolism, and it had been hoped that heightened end-tidal carbon monoxide concentration would serve as a useful marker of the rate of bilirubin production (Stevenson 2001). Measuring this parameter has not proved to be a reliable predictor of significant hyperbilirubinaemia.

Early-onset visible jaundice within the first 24 hours of life may be associated with a pathological cause of jaundice and is an important risk factor for subsequent significant hyperbilirubinaemia. The bilirubin level should be interpreted urgently. This should be done taking into account the baby's postnatal age in hours, and not by rounding up or down in days (or becoming confused as to whether the baby is day 0 or day 1). The UK NICE guideline provides a treatment threshold table (Fig. 29.9) and a graph for babies of greater than 38 weeks' gestation. An implementation tool (Bili-wheel) is being developed to display the same thresholds and to assist in precise measurement of a baby's age in hours (Table 29.5). For the preterm babies between 23 and 37 weeks' gestation there are specific graphs by week of gestation (Fig. 29.10) providing guidance on thresholds for phototherapy and exchange transfusion (National Institute for Health and Clinical Excellence 2010).

The differential diagnosis of unconjugated jaundice

The maternal records should be checked for documentation of syphilis and hepatitis serology as well as any history suggesting congenital infection. Specific red cell morphological abnormalities, such as spherocytosis, or inborn errors of metabolism, such as galactosaemia or Crigler–Najjar syndrome types I and II, may be implicated from the family history. The jaundice associated with galactosaemia is likely to be predominantly unconjugated in the first week of life. Diagnostic pointers such as hepatomegaly, poor feeding and vomiting should prompt early screening for galactosaemia with urinalysis for non-glucose-reducing substances (Clini-test) and assessment of erythrocyte galactose-1-phosphate uridyl transferase activity.

The Crigler–Najjar syndromes present characteristically in the first few days of life with a rapidly evolving, non-haemolytic, unconjugated hyperbilirubinaemia. The type I disorder results from a complete absence of UDPGT within the hepatocyte and is inherited in an autosomal recessive manner. Affected individuals frequently require exchange transfusions in the newborn period and nocturnal phototherapy in early childhood. Definitive treatment involves liver transplantation. Crigler–Najjar syndrome type II is a less severe condition in that there is partial UDPGT activity. Inheritance is

thought to be autosomal dominant with variable expression, and serum bilirubin levels can be adequately controlled with a UDPGT inducer such as phenobarbital.

With parents of Mediterranean, Asian and African ethnicity, the increased likelihood of G6PD deficiency, especially in males, needs to be considered. Screening cord blood for evidence of G6PD deficiency may be appropriate in populations with a high incidence of this condition. It should be remembered that G6PD levels can be falsely elevated in the context of a high reticulocyte count, and so may need to be repeated at 2–3 months of age. The jaundice in affected babies usually evolves at 3–5 days of age. The differing severity of jaundice probably reflects the variety of isoenzyme deficiencies. The pronounced jaundice in neonates with G6PD deficiency may also result from an associated partial defect in bilirubin conjugation (Kaplan and Hammerman 2002). This would be in keeping with the fact that end-tidal carbon monoxide measurements have failed to demonstrate appreciable early haemolysis in such infants (Seidman et al. 1995). An affected individual is at risk of haemolytic episodes triggered by a number of common drugs. Parents and family practitioners should be given a list of medications to avoid Table 30.6 (in Haematology chapter).

Details of gestational age and evidence of birth asphyxia and trauma may explain heightened or prolonged jaundice. The mode and success of feeding should be noted and assessment made of the infant's state of hydration and weight trend since birth. Examination of the newborn should confirm gestational age and identify growth retardation. Polycythaemia, anaemia, hydrops, purpura and frank bruising should be looked for, along with general signs of infection.

A full infection screen is not an automatic requirement for cases of hyperbilirubinaemia in otherwise well newborns, but a low threshold for performing a full infection screen should be adopted. No instance of bacterial septicaemia was identified from a study reporting the investigation of over 300 newborns readmitted with a mean peak serum bilirubin level of 316 $\mu\text{mol/l}$ (range 217–498 $\mu\text{mol/l}$) (Maisels and Kring 1992). Failure of unconjugated hyperbilirubinaemia to respond to phototherapy should alert the clinician to the possibility of infection (Linder et al. 1988).

Prolonged jaundice

Visibly detectable jaundice beyond 2 weeks of age in the term infant and 3 weeks in the preterm is classified as 'prolonged jaundice'. The majority of term infants presenting with prolonged jaundice have an unconjugated hyperbilirubinaemia and will be breastfeeding. Providing there are no features in the history or on clinical examination that suggest a pathological cause (in particular, the urine is not dark, stool colour is not pale and chalky, there is no hepatomegaly and the baby is thriving), screening investigations can be delayed until 3 weeks of age. Some babies will have cleared their jaundice by then but if it persists the total and conjugated serum bilirubin must be determined. Some or all of the following tests may be appropriate:

- full blood count
- examination of blood film if haemolysis is suspected
- blood group and DAT (mother's group and antibody status should be known)
- thyroid function tests if result of heelprick thyroid-stimulating hormone screen is not known
- urinalysis for reducing sugars (Clinitest)
- urinalysis for evidence of infection.

Further tests (Table 29.4 and see Chapter 29, part 2) will be indicated according to the outcome of this initial screen. A conjugated

Progressive familial intrahepatic cholestasis
Inspissated bile plug syndrome
Galactosaemia
Tyrosinaemia

bilirubin level $>25 \mu\text{mol/l}$ is abnormal and merits urgent further investigation to exclude serious liver disease, such as biliary atresia.

Cholestatic or conjugated jaundice

Definitions of conjugated hyperbilirubinaemia vary. A serum conjugated bilirubin level of above 25 $\mu\text{mol/l}$ is a commonly adopted cut-off. A threshold level definition of up to 10% or 20% of the total serum bilirubin may provide false reassurance in the case of total levels in excess of 250 $\mu\text{mol/l}$, and should be avoided. Pale chalky (acholuric) stools and dark bile-stained urine are the clinical markers of established conjugated jaundice, but neither may be present in the first weeks of many hepatic disease states, including biliary atresia.

Diagnosis of any associated clotting abnormality and its correction are urgent considerations in the infant with conjugated jaundice. Several conditions present with a mixture of raised unconjugated and conjugated bilirubin. Notable amongst these are the intrauterine infections, bacterial sepsis, galactosaemia, aminoacidaemias and congenital hypopituitarism. Some of the causes of conjugated hyperbilirubinaemia are listed in Table 29.6, and the initial investigations are found in Table 29.4.

If an obstructive aetiology is suspected, liver ultrasound and a hepatobiliary excretion study will be indicated. Visualisation of the gallbladder on ultrasound does not rule out biliary atresia. The importance of making an early diagnosis of biliary atresia and its prompt referral to a centre specialising in the medical and surgical management of childhood liver disorders cannot be overstated. Conjugated hyperbilirubinaemia is further described in Chapter 29, part 2.

Clinical management of the jaundiced infant

Management of neonatal jaundice should commence with prevention. Adequate support should be provided to all mothers as they

establish their baby's early feeding pattern. In the case of breastfeeding mothers, support in establishing successful lactation and feeding will reduce the likelihood of jaundice reaching levels requiring treatment. The importance of this practical assistance is reinforced in the NICE clinical guideline Routine Postnatal Care of Women and their Babies (National Institute of Health and Clinical Excellence 2006).

The different potential modes of treatment of unconjugated jaundice that have been advocated are shown in Table 29.7. The established treatments are phototherapy, exchange transfusion and high-dose intravenous immunoglobulin (IVIG) to suppress isoimmune haemolysis. Unconjugated hyperbilirubinaemia that is judged to be above treatment thresholds, but below those that prompt immediate exchange transfusion, can usually be controlled using phototherapy. A lack of response to optimal phototherapy may imply significant underlying haemolysis, necessitating exchange transfusion. Any infant undergoing treatment for jaundice should be adequately investigated for the cause. An infant with a total serum bilirubin level that is rising towards or has already reached or exceeded an exchange transfusion threshold should have blood urgently cross-matched for the procedure. This is a neonatal emergency and an appropriate response time from the local transfusion service should be established and audited.

Phototherapy

Observation of the effect of sunlight on the serum bilirubin level of premature infants nursed outdoors prompted the first use of a 'cradle illumination machine' (Cremer *et al.* 1958). It took a decade for phototherapy to gain clinical acceptance throughout the world, and a further 12 years before its mode of action started to be unravelled (McDonagh *et al.* 1980). Phototherapy of itself has not influenced neurodevelopmental outcome or cognitive performance in recipients (Seidman *et al.* 1994; Scheidt 1991), but it remains a convenient and safe means of lowering serum bilirubin. Most importantly, phototherapy reduces the need for the more hazardous alternative, namely exchange transfusion. Optimal use of phototherapy in preterm neonatal jaundice has made the need to resort to exchange transfusion in that context a rarity (Maisels and Watchko 2003).

The ease of use of phototherapy has encouraged its overuse. Many infants are 'placed under the lights' unnecessarily or treated for too long. The vogue for 'prophylactic' phototherapy from birth in very-low-birthweight infants has been shown to neither reduce the peak nor shorten the duration of their jaundice (Curtis-Cohen *et al.* 1985). Phototherapy would only appear to be effective as bilirubin enters the skin at serum levels $>80 \mu\text{mol/l}$ (Tan 1982). The maximal effect of phototherapy is during the first 24–48 hours of its use. It is to be anticipated that, in the absence of haemolysis, phototherapy will reduce the serum bilirubin level by 25–50% during this initial phase. It has been suggested that the enterohepatic circulation of

bilirubin- Z_e, Z_e , reconstituted from configurational photoisomers in bile, causes the subsequent decay in response.

Phototherapy has a benign reputation but it is not without side-effects. The more commonly encountered are:

- diarrhoea
- increased fluid loss via the skin
- temperature instability
- erythematous rashes
- tanning
- bronze-baby syndrome.

The diarrhoea associated with phototherapy is thought to result from an irritant effect of photoisomers on the bowel. This and increased insensible water loss from the skin require attention to fluid balance. Individualised assessment of fluid requirements, especially in the premature or sicker infant, rather than a general prescription of additional fluid is to be advised. The NICE guideline on routine postnatal care recommends that 'breastfed babies should not be routinely supplemented with formula, water or dextrose water for the treatment of jaundice' (National Institute of Health and Clinical Excellence 2006). Close attention to thermoregulation is important, with the risks of cooling from surface exposure and overheating from standard phototherapy lamps. Nursing care should include regular monitoring of the infant's temperature, documentation of stool frequency and urine output, and a daily assessment of weight. The eyes of an infant receiving lamp phototherapy should be shielded to prevent potential retinal damage.

In vitro evidence of light-induced DNA damage, particularly in the presence of bilirubin, has not been mirrored by a consistent increase in melanocytic naevi in recipients of phototherapy, including children receiving long-term treatment for Crigler-Najjar syndrome. The bronze-baby syndrome results from an interaction between cholestatic jaundice and phototherapy (Onishi *et al.* 1982). The brown pigment produced (bilifuscin) stains the infant's skin and lingers for some weeks after phototherapy has been discontinued. There are case reports of the rare complication of bullous skin lesions resulting from transient porphyriaemia in such cases (Mallon 1995).

The recently developed fiberoptic systems for delivering phototherapy via a body pad or wrap have made its application more versatile. Earlier trials have shown fiberoptic phototherapy to be as effective as conventional phototherapy in preterm infants, but less so in term infants (Mills and Tudehope 2003). Larger fiberoptic pads or nests designed for term infants are currently in use and should be subjected to comparative trials. A new generation of phototherapy unit has evolved using the technology of multiple light-emitting diodes. These have the advantage of not emitting infrared or ultraviolet radiation, and so can be used closer to the infant's skin for maximal efficacy (Seidman *et al.* 2000). Placing halogen lights closer to the baby's skin than the manufacturer's guidance may cause skin burns.

Optimal use of phototherapy

The efficacy of phototherapy depends on the dose and wavelength of light used and the proportion of the infant's surface area to which it is applied. The dose of phototherapy administered is expressed in terms of spectral irradiance ($\mu\text{W}/\text{cm}^2/\text{nm}$) in the 430–490-nm band. Before the mode of action of phototherapy was better understood, it was thought that saturation of dose-response occurred within the blue light range at a spectral irradiance of $4 \mu\text{W}/\text{cm}^2/\text{nm}$. This is true of the configurational isomer bilirubin- Z_e, E , but production of what is thought to be the more important photoisomer, lumirubin, has a dose-response relationship that does not attain

saturation until a spectral irradiance of 25–30 $\mu\text{W}/\text{cm}^2/\text{nm}$ is achieved (Ennever 1992).

Early phototherapy lights were designed to emit blue light at a wavelength of around 450 nm, in keeping with the maximal absorbance pattern of bilirubin. Pure blue light is poorly tolerated by staff and can mask cyanosis in an infant. Combinations of broad-spectrum white light and blue light have proved more acceptable. There are theoretical reasons why green light delivered at high irradiance would be the most efficient choice. Compared with blue light, green preferentially favours formation of lumirubin, the main excretory photoisomer, and its longer wavelength enhances skin penetration (Ennever 1990, 1992).

When single-lamp phototherapy is used, parents can be reassured that in taking their baby out of the lights briefly for feeds and cuddles they are not jeopardising treatment. The efficiency of treatment can be improved by using more than one phototherapy lamp or by combining conventional overhead lamps with a fiberoptic system beneath the baby. This multiple phototherapy, applied to a greater proportion of the body surface area, should be adopted in cases of jaundice if the serum bilirubin fails to respond to single phototherapy, is less than 50 $\mu\text{mol}/\text{l}$ below the threshold for exchange transfusion or is rising rapidly ($>8.5 \mu\text{mol}/\text{l}/\text{h}$). It may prove necessary for the baby to be naked with the exception of eye pads. The American Academy of Pediatrics (AAP) defines intensive phototherapy as a spectral irradiance of at least 30 $\mu\text{W}/\text{cm}^2/\text{nm}$ over the relevant bandwidth (American Academy of Pediatrics 2004). Increasing the dose of phototherapy is most readily achieved by operating the light sources at the minimum safe distance from the infant placed on an overhead cot. Other measures, such as reflecting light back on to the baby with aluminium foil or white drapes, have been recommended, but care should be taken not to obscure the baby from observation.

Pharmacological agents

Synthetic metalloporphyrins have the potential to reduce bilirubin production through competitive inhibition of haem oxygenase. Tin protoporphyrin has been shown to modify the course of hyperbilirubinaemia and to avoid the need for phototherapy in term and near-term newborns (Kappas et al. 1995). Despite its early promise this approach to therapy is currently not advocated.

A preventive therapy that has entered practice is administration of high-dose IVIG to newborns presenting with severe rhesus or ABO isoimmunisation. Treatment of these conditions with IVIG has been shown to reduce significantly the need for exchange transfusion, the duration of phototherapy and the length of hospital stay (Gottstein and Cooke 2003). Babies treated in this way are more likely to require top-up red cell transfusions for late anaemia. As a precaution against overuse of a pooled human blood product it is recommended that a 0.5 g/kg dose of IVIG should be given over 4 hours to babies with a serum bilirubin that continues to climb at a rate $>8.5 \mu\text{mol}/\text{l}/\text{h}$ despite multiple phototherapy (National Institute for Health and Clinical Excellence 2010). The majority of cases of ABO incompatibility are amenable to multiple phototherapy if delivered optimally. A more pre-emptive use of IVIG may be called for in cases of severe rhesus disease where there has been little or no in utero management, or cases of ABO incompatibility readmitted with a serum bilirubin level approaching exchange values.

Inducers of hepatic conjugation and agents that decrease the enterohepatic recirculation of bilirubin have been studied extensively for their ability to influence the severity and time course of neonatal jaundice significantly. These and other therapies such as traditional Chinese medicine, acupuncture and homeopathy

have been considered during compilation of the UK NICE neonatal jaundice guideline and are currently not recommended (National Institute for Health and Clinical Excellence 2010).

Exchange transfusion

The practicalities of performing an exchange transfusion are covered elsewhere (Ch. 30). The need for exchange transfusion has reduced, as a result of improved in utero management and more effective phototherapy. In cases where there has been severe in utero haemolysis, early exchange may be required to correct anaemia and to remove sensitised red cells and circulating antibodies. Previous guidelines based on cord blood values now rarely apply, as most infants with severe rhesus disease will have received in utero transfusion, although a cord blood bilirubin level of more than 90 mmol/l and/or a cord blood haemoglobin level of less than 10 g/dl are still important indications that an early exchange transfusion is required. In babies who received multiple fetal transfusions information regarding how recent the transfusion was and an estimation of the proportion of fetal red cells in the baby's circulation (Kleihauer test) will govern the need for an early exchange. Many such infants respond to intensive phototherapy followed by a later top-up transfusion. If, despite multiple phototherapy, the serum bilirubin continues to rise by $>8.5 \mu\text{mol}/\text{l}/\text{h}$, high-dose IVIG is indicated, as discussed above. Exchange transfusion will be indicated if these measures fail and cross-matched blood should be made available for this eventuality. Whilst it would appear logical to keep the serum albumin level of a jaundiced infant within the normal range (Ahlfors 1994), there is no evidence that the practice of giving albumin routinely before or during an exchange transfusion confers benefit (Dennerly 2002). Similarly, there is no evidence to support the routine giving of intravenous calcium during an exchange transfusion (National Institute for Health and Clinical Excellence 2010).

In addition to a small risk of blood-borne infection, exchange transfusion carries a significant risk of morbidity and mortality from vascular accidents, cardiac complications, biochemical and haematological disturbance (Keenan et al. 1985). The overall mortality rate from the procedure is quoted as being 0.3% and morbidity 5%. These figures originate from a well-conducted trial performed during an era when exchange transfusion was more commonly performed (Scheidt et al. 1990). The rate of complications is higher in sick premature newborns and lower in otherwise well term or near-term infants (Jackson 1997). Exchange transfusions are now rarely required, and so, with dwindling practical expertise, the procedure is likely to have become more hazardous. Simulation training can be usefully applied to rehearsal of the technique and familiarisation with the equipment and desired monitoring.

Exchange transfusion will remain necessary for infants who fail to respond to optimal phototherapy or who present late with bilirubin levels in excess of a given exchange value. In the latter case, the infant should be placed under multiple phototherapy, and cross-matched blood should be sought as a matter of urgency for an anticipated exchange transfusion. Attention should be paid to correcting disturbances of hydration or acid-base balance, and to the treatment of any underlying infection. Should the serum bilirubin fall below the exchange transfusion level by the time the blood is available a decision as to whether to go ahead with the exchange or not has to be made. This may be informed by the peak serum bilirubin, the duration of jaundice, the bilirubin/albumin ratio and the clinical status of the baby. Signs and symptoms of acute bilirubin encephalopathy are an absolute indication to proceed with an exchange transfusion.

Guidelines for the use of phototherapy and exchange transfusion

Premature infants

Formerly, no distinction was made between the thresholds for treatment of jaundiced term and preterm babies. Kernicterus is known to occur at lower levels of bilirubin in those born prematurely. This is not related to immaturity of the blood–brain barrier, as was once thought, but is more likely to reflect lower levels of albumin with altered binding properties in the sick infant. Recognition that preterm newborns are at higher risk of bilirubin toxicity has given rise to sliding scales prompting earlier intervention on the basis of lower birthweight or gestational age. It would appear prudent to maintain a greater safety margin in the smaller, less mature infant, but a counterargument holds that it may be beneficial to allow a premature infant to have a moderate degree of jaundice to take advantage of bilirubin's antioxidant properties (Yeo et al. 1998). A trial comparing 'aggressive' and 'conservative' phototherapy regimes for infants weighing 1000 g or less (extremely low birthweight) did not show a significant difference in the primary outcome measure of death or neurodevelopmental impairment (Morris et al. 2008). The 'aggressive' phototherapy commenced at a threshold of 85 $\mu\text{mol/l}$. Outcome in terms of rates of necrotising enterocolitis and retinopathy of prematurity were not different, but subgroup analysis suggested that 'aggressive' phototherapy was associated with a reduction in neurodevelopmental impairment in infants with birthweights of 751–1000 g. An increase in mortality observed

in those with a birthweight of 501–750 g treated with 'aggressive' phototherapy raises a note of caution.

Practice in the USA has tended to adopt birthweight categories for the sliding scale of treatment thresholds for jaundice in the premature infant (Maisels and Watchko 2003; Watchko and Maisels 2010). In the UK gestational age categories for treatment are more readily used, but hitherto this has been haphazard with no national consensus (Rennie et al. 2009). The UK NICE guideline on neonatal jaundice (National Institute for Health and Clinical Excellence 2010) recommends treatment thresholds that are specific by week of gestational age for babies of less than 38 weeks' gestation. For the purpose it provides a novel adjustable Excel spreadsheet (Fig. 29.11). A rule of thumb that has been in use for some years in many UK hospitals has been adopted to determine the thresholds for phototherapy and exchange transfusion, using the simple formulae:

- for phototherapy: bilirubin in $\mu\text{mol/l}$ = (gestational age \times 10) – 100
- for exchange transfusion: bilirubin in $\mu\text{mol/l}$ = (gestational age \times 10).

It is recommended that these should be used as the treatment level for babies aged 72 hours or older. Use of these simple formulae produces thresholds for phototherapy and exchange transfusion that do not represent a significant departure from mainstream practice in the UK (Rennie et al. 2009), or from values described as 'conservative' in the USA (Morris et al. 2008). The threshold levels for the first 72 hours of life were determined by drawing straight lines from 40 and 80 $\mu\text{mol/l}$ at birth to the formula-based level at 72 hours. The start values were chosen to reflect the upper limit of

Fig. 29.11 Example of Excel spreadsheet: 27 weeks' gestation (National Institute for Health and Clinical Excellence or University College London (UCL) version) (devised by Dr Giles Kendall, Dr Janet Rennie and Professor T J Cole at UCL).

normal for the umbilical cord blood bilirubin in the absence of haemolysis and a level that is likely to be associated with significant in utero haemolysis.

There is currently insufficient evidence to support a further reduction in thresholds based on risk factors. The outcome of a recently completed trial looking at the use of the bilirubin/albumin ratio as an adjunct to decision-making on thresholds for phototherapy and exchange transfusion in preterm infants of less than 32 weeks' gestation may guide practice in this area (BARTrial: <http://www.controlled-trials.com/iscrt/pf/74465643>). The NICE guideline also provides advice on monitoring, intensifying and stopping phototherapy treatment (Fig. 29.12).

Term infants

Over the past 15–20 years, there has been a relaxation in the UK of the threshold for phototherapy for healthy jaundiced term newborns from 250 to 300–350 $\mu\text{mol/l}$, and for exchange transfusion from 340 to 400–450 $\mu\text{mol/l}$. The fact that healthy term babies appear to tolerate higher levels of bilirubin than their haemolysing or sick contemporaries has prompted calls for a more relaxed approach to the management of their jaundice. The so-called 'kinder, gentler approach' to the jaundiced term infant proposed by Newman and Maisels (1992) was further developed in a 'practice parameter' issued by a subcommittee of the AAP (American

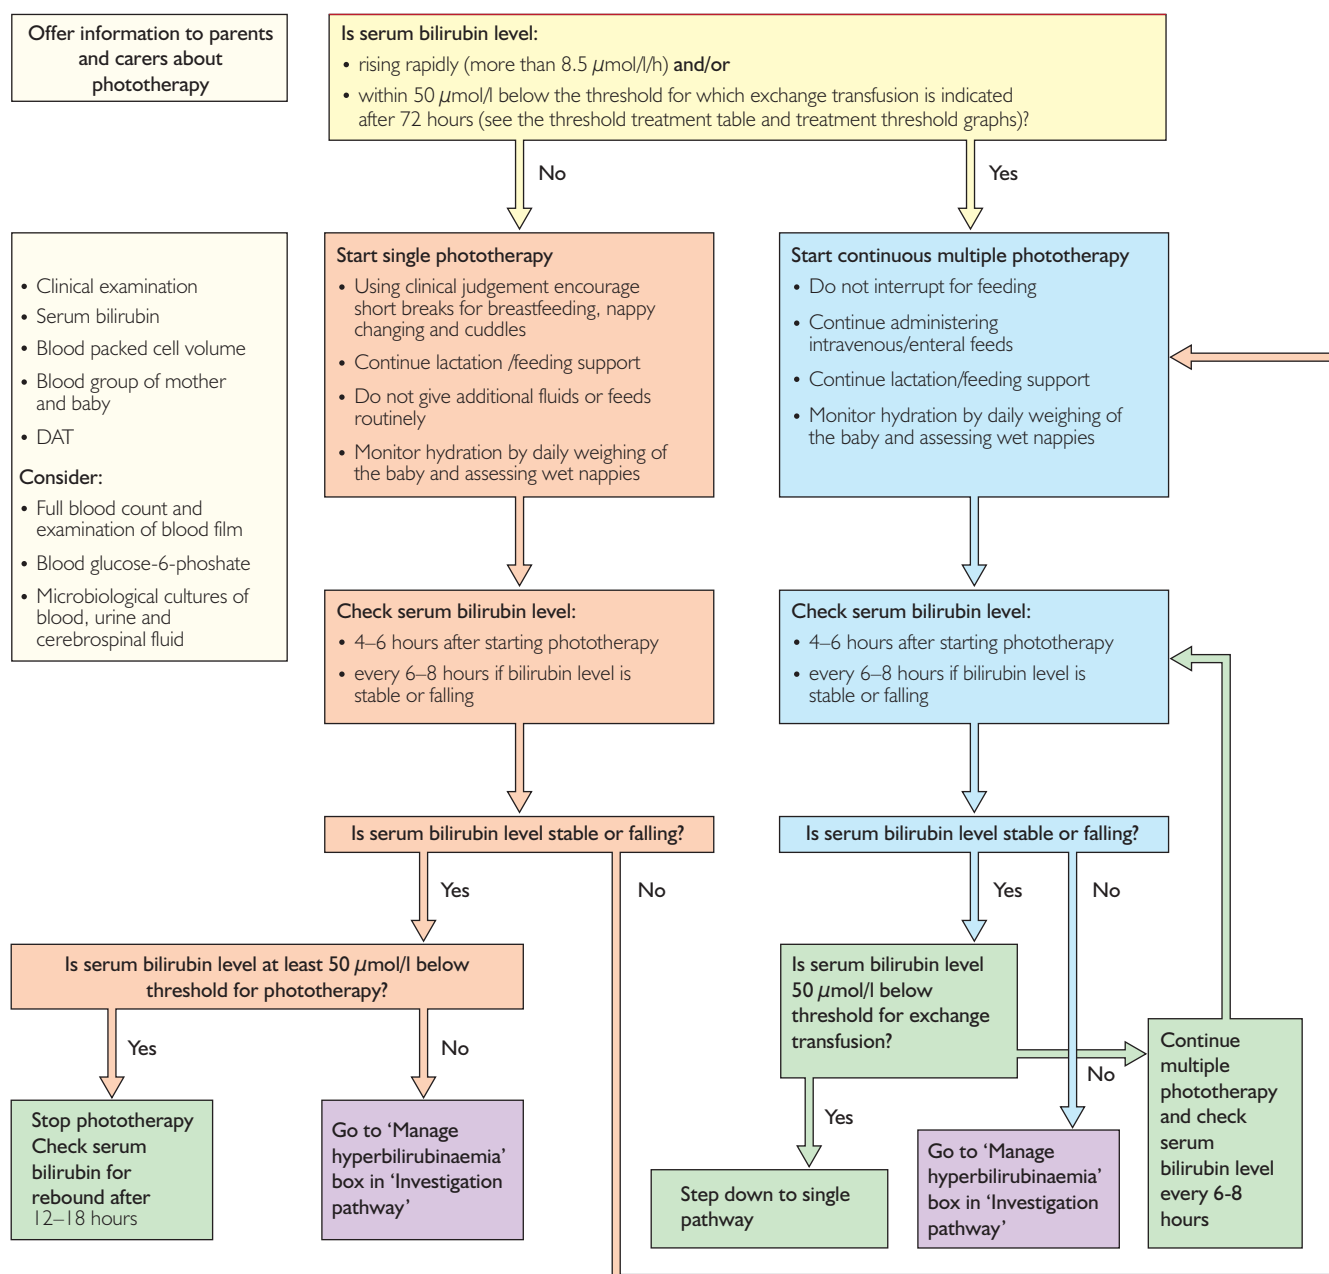

Fig. 29.12 National Institute for Health and Clinical Excellence phototherapy pathway pathway.

Academy of Pediatrics 1994). When this was applied to otherwise healthy full-term infants in the USA it was associated with a decrease in the use of phototherapy by more than 50% and of exchange transfusion by 87% (Seidman et al. 2001), and may have saved as many as 200 lives each year in the USA from procedural complications (Watchko 2001). Subsequently there was evidence that the 1994 guidelines were being 'stretched' to apply to treatment in near-term infants with gestational ages of 35 weeks and above (Seidman et al. 2001; Bhutani and Johnson 2006) and amongst term infants the recommended phototherapy thresholds were not being adhered to (Atkinson et al. 2003). The AAP subcommittee on hyperbilirubinaemia revised its practice parameter by issuing warnings on risk factors for severe jaundice and the clinical pitfalls that may result in kernicterus (American Academy of Pediatrics 2001), and went on to issue a further clinical practice guideline on the management of hyperbilirubinaemia in newborn infants of 35 or more weeks' gestation (American Academy of Pediatrics 2004). This document in turn has been updated with clarification that places emphasis on lowering treatment thresholds in the presence of listed risk factors (Maisels et al. 2009b). Cases of kernicterus have not been reported in infant populations managed with adherence to the AAP guidelines (Newman 2003), and there does not appear to have been a significant change in the reporting of kernicterus cases in the USA across this era of adopting the 'kinder, gentler approach' (Burke et al. 2009).

For babies born at 38 or more weeks' gestation, the UK NICE guideline on neonatal jaundice recommends consensus-derived thresholds for initiation of phototherapy from 96 hours of age of 350 $\mu\text{mol/l}$ and for exchange transfusion of 450 $\mu\text{mol/l}$ (National Institute of Health and Clinical Excellence 2010). For the period from birth to 96 hours of age a series of bilirubin levels with 6-hourly stepwise increases at which phototherapy and exchange transfusion are recommended has been tabulated (Fig. 29.9); in addition to the phototherapy pathway there is also a pathway for exchange transfusion (Fig. 29.13). These phototherapy and exchange transfusion thresholds are comparable to the most commonly reported values in a recent survey of practice in the UK (Rennie et al. 2009) and with the thresholds adopted by the AAP (American Academy of Pediatrics 2004).

Most treatment guidelines rely on total bilirubin level, but, faced with the decision as to whether or not to perform an exchange transfusion, some paediatricians have adopted the practice of subtracting the conjugated component. This should be avoided as there are unnerving case reports of kernicterus occurring in such circumstances (Bertini et al. 2005), as well as the possibility that conjugated bilirubin can displace unconjugated bilirubin from albumin. The current national guidelines in the USA (American Academy of Pediatrics 2004) and the UK (National Institute for Health and Clinical Excellence 2010) recommend adherence to treatment thresholds based on the total serum bilirubin. Specialist advice

Exchange transfusion pathway

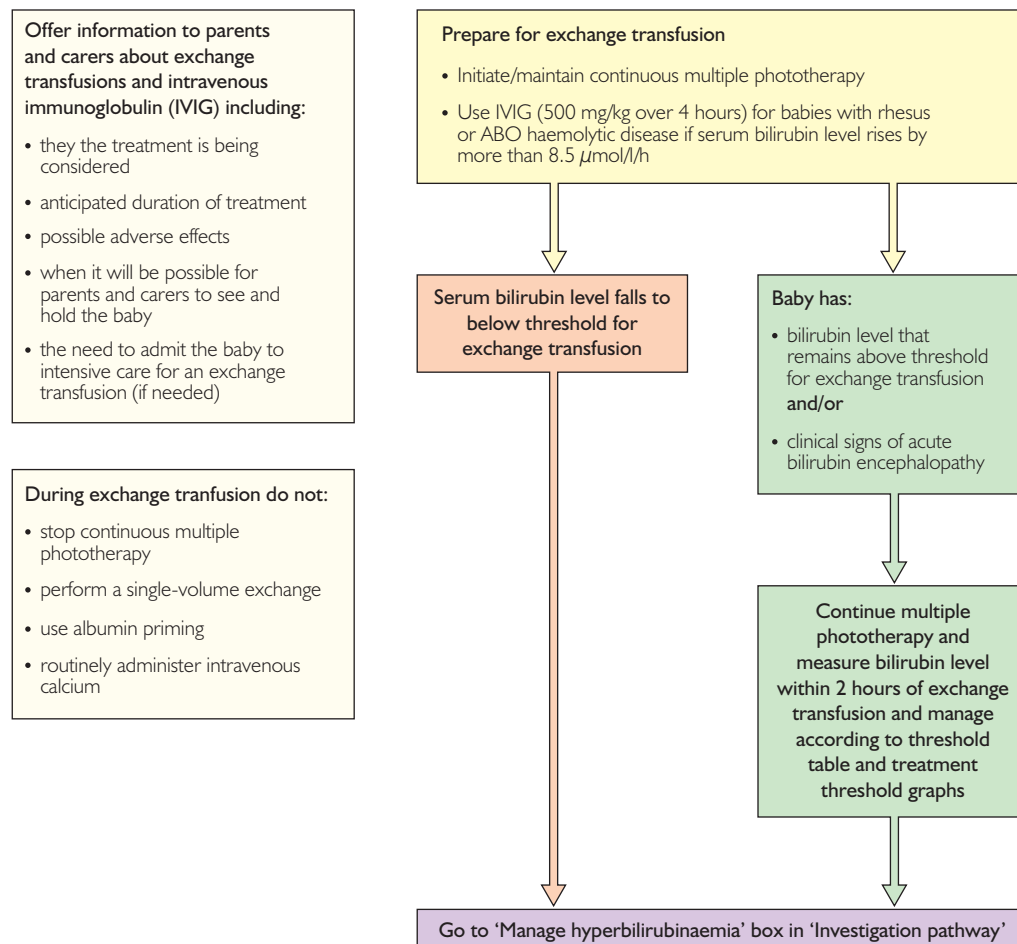

Fig. 29.13 National Institute for Health and Clinical Excellence exchange transfusion pathway.

should be sought for the exceptional cases in which the conjugated bilirubin is more than 50% of the total.

The latest American guidelines (American Academy of Pediatrics 2004; Maisels et al. 2009b) recommend reducing the thresholds for phototherapy and exchange transfusion by 40–50 $\mu\text{mol/l}$ in cases where there are additional risk factors, defined as isoimmune haemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis and hypoalbuminaemia ($<30 \text{ g/l}$). They also suggest that 'bilirubin/albumin ratios can be used together with but not in lieu of the total serum bilirubin level as an additional factor in determining the need for exchange transfusion'.

It is also important to heed the recommendations made on the mode of phototherapy and the intervals between monitoring the serum bilirubin laid out in the recent guidelines. The UK NICE guideline recommends that, after starting phototherapy, the serum bilirubin is checked 4–6-hourly until the bilirubin level is stable or falling and every 6–12 hours thereafter. Multiple phototherapy, using more than one overhead source or in combination with a fiberoptic device of appropriate size for the baby, is recommended if the serum bilirubin is within 50 $\mu\text{mol/l}$ below the threshold for which exchange transfusion is indicated. Multiple phototherapy should also be adopted when the bilirubin is rising rapidly (more than 8.5 $\mu\text{mol/l/h}$) despite single phototherapy. When the serum bilirubin has fallen to more than 50 $\mu\text{mol/l}$ below the exchange transfusion threshold a stepdown from multiple phototherapy to single phototherapy should be considered. This should be performed with caution in the presence of known or suspected haemolysis, and monitored with a repeat serum bilirubin within 4–6 hours. When the serum bilirubin has fallen to more than 50 $\mu\text{mol/l}$ below the phototherapy threshold, single phototherapy can be stopped. A serum bilirubin should be checked for rebound after 12–18 hours (National Institute for Health and Clinical Excellence 2010).

Population surveillance and future monitoring of best practice

In the USA a case is being made for universal hour-specific predischarge bilirubin screening to identify babies at risk of significant hyperbilirubinaemia (Maisels et al. 2009b). The accuracy of this prediction will be enhanced by taking into account the additional

risk factors of prematurity and intention to breastfeed exclusively (Maisels et al. 2009a). Given that such an approach has been shown to reduce the incidence of a total serum bilirubin level of $>427 \mu\text{mol/l}$ ($>25 \text{ mg/dl}$), it may be anticipated that a reduction in the incidence of kernicterus can be achieved (Kuzniewicz et al. 2009).

In the UK the responsibility for detecting significant postdischarge jaundice rests with the primary healthcare team of midwives, health visitors, general practitioners and, of course, informed parents. The NICE guideline (National Institute for Health and Clinical Excellence 2010) seeks to inform parents better, and to alert the primary healthcare team to babies at heightened risk of significant hyperbilirubinaemia. These babies will have an additional assessment in the period leading up to 48 hours of age with inspection for signs of jaundice and attention to feeding support. A clear directive has been made to test, rather than guess, the level of bilirubin in all babies presenting with neonatal jaundice. This approach is reliant on our ability to recognise better clinical jaundice in babies with darker skin tone, who are currently overrepresented in registries of kernicterus and surveys of hyperbilirubinaemia.

Clinical kernicterus is an irreversible tragedy that should be considered a preventable condition in the term and near-term infant. National registries of cases of acute bilirubin encephalopathy and chronic kernicterus should be established to monitor adherence to national guidelines and to benchmark their impact. There are calls in the USA to designate a total serum bilirubin level $>427 \mu\text{mol/l}$ ($>25 \text{ mg/dl}$) as a reportable condition (Bhutani and Johnson 2009b). In the UK it is being proposed that kernicterus be added to the list of 'never events' incurring contractual penalties within the quality goals and sanctions of the present-day National Health Service (<http://neverevents.dh.gov.uk>). It could be argued that the 'never event' trigger should be an unconjugated serum bilirubin value in excess of 510 $\mu\text{mol/l}$, a level above which one in eight babies are at risk of developing signs of acute bilirubin encephalopathy, of whom as many as half may go on to develop chronic kernicterus (Manning et al. 2007). In the UK a repeat national survey of hyperbilirubinaemia $>510 \mu\text{mol/l}$ and treatment threshold practice should be conducted after implementation of the 2010 NICE guidance. If preventable cases of kernicterus continue to occur the alternative approach of universal screening may need to be considered.

Part 2: Liver disease

Giorgina Mieli-Vergani Nedim Hadžić

Introduction

Liver disease in infancy is rare but represents a serious cause of morbidity and mortality. A better awareness of the causes of liver disease in this age group and their mode of presentation has led to earlier diagnosis of treatable conditions, with considerable improvement in outcome, and facilitated genetic counselling for those families with hereditary disorders.

Jaundice is usually the first sign of liver dysfunction, but its importance is often underestimated because of the frequent occurrence of physiological jaundice in the neonatal period (see Ch. 29 part 1). A raised serum bilirubin with a conjugated component of >20% and urine which contains bile pigment is always pathological. The notion that jaundice could be due to liver disease should prompt health workers to assess the colour of the urine and the stools to ascertain whether the jaundice is due to cholestasis. A neonate's urine is usually pale yellow and often colourless. Dark yellow urine (unless during phototherapy) and pale stools which are not yellow or green in an infant of any age should suggest liver disease and should prompt medical review and appropriate investigation (National Institute for Health and Clinical Excellence 2010). A persistently elevated unconjugated bilirubin, not explained by haemolysis or other neonatal problems, suggests the possibility of liver-based inherited disorders of bilirubin metabolism.

Hepatitis syndrome of infancy

Hepatitis syndrome of infancy is characterised by clinical and laboratory features of liver dysfunction, of which the most distinct is conjugated hyperbilirubinaemia. Babies usually have inflammatory changes in the liver histology – hence the name hepatitis – but the cause is only rarely infective. In most cases the baby presents with conjugated jaundice, which follows physiological jaundice; the urine becomes dark and the stools pale. Less commonly, babies may present with complications of liver dysfunction such as a bleeding diathesis, hypoglycaemia or fluid retention. The bleeding diathesis is usually due to vitamin K deficiency associated with fat malabsorption, which may also cause failure to thrive. Unless parenteral vitamin K is given, these babies may bleed catastrophically. Hepatomegaly is almost universal. Palpable splenomegaly occurs in 40–60% of cases.

Hepatitis syndrome of infancy most commonly is due to intrahepatic disease, for which there are many associated disorders. It may also be due to lesions of the biliary system. All babies require urgent investigation to identify disorders for which there is specific treatment and to prevent complications of cholestasis. If the stools contain no yellow or green pigment, cholestasis is complete and surgical conditions, including biliary atresia, must be suspected. It is essential to arrange urgent referral to a specialist centre which has the experience and skills to confirm the diagnosis and provide corrective surgery as early as possible (Mieli-Vergani et al. 1989).

Pathology

Four main pathological entities cause the syndrome:

1. hepatocellular disease (hepatitis)
2. inflammation and bile duct damage, leading in some instances to paucity of interlobular bile ducts

3. disorders of the main intrahepatic bile ducts, leading to sclerosing cholangitis
4. disorders of the extrahepatic bile ducts, most commonly biliary atresia.

Hepatocellular disease may be associated with a wide range of infective, genetic, endocrine, vascular, toxic, familial, genetic or chromosomal disorders (Vara and Dhawan 2007). Often there are no associated factors and the disorder is cryptogenic. Chronic liver disease rarely follows in infective or endocrine disorders, but occurs in at least 50% of genetic or familial disorders. Pathological categories 2–4 are invariably associated with chronic liver disease unless surgery (for some disorders in category 4) is effective. Infants with a normal serum gamma-glutamyl transpeptidase (GGT) activity or cholesterol concentration in the presence of jaundice and abnormal biochemical tests of liver function are likely to have a form of progressive familial intrahepatic cholestasis or primary bile acid synthesis abnormality (Clayton et al. 1987, 1995; Maggiore et al. 1987; Thompson and Jansen 2000; Subramaniam et al. 2010). Together with babies with sclerosing cholangitis (Amedee-Manesme et al. 1987; Baker et al. 1993), this group often develops severe chronic liver disease.

For all pathological entities, in the acute stages, the intrahepatic pathology, as revealed by liver biopsy, is dominated by cholestasis, with variable degrees of giant-cell transformation of hepatocytes and inflammatory cell infiltrate in the portal tracts (Clayton et al. 1987, 1995). In metabolic disorders, abnormal accumulation of microvesicular or macrovesicular fat, glycogen or other storage material may be found in hepatocytes or Kupffer cells. Portal tract widening with oedema, accumulation of fibrous tissue and bile duct proliferation is characteristic of disorders of the major bile ducts, the most common of which is biliary atresia. It may occur in genetic disorders such as α_1 -antitrypsin deficiency (α_1 ATD) and could be a harbinger of chronic liver disease.

Clinical features

The majority of babies with hepatitis syndrome present with conjugated hyperbilirubinaemia starting in the first 4 weeks of life, but may occasionally present as late as 4 months of age. The second most common presentation is spontaneous bleeding, usually secondary to vitamin K malabsorption; the jaundice may be mild or ignored because it is considered physiological by parents and their healthcare advisers. Rarely, babies present with features of hypoglycaemia or hypoalbuminaemia. Review of the perinatal case records and past medical history may reveal features suggesting intrauterine infection, exposure to toxins, drugs or intravenous nutrition, familial, genetic or metabolic disease, or consanguinity (Vara and Dhawan 2007).

Clinical examination is likely to show mild hepatomegaly and splenomegaly. Neonates with intrahepatic disease may show failure to thrive, but babies with biliary atresia typically are well nourished and have no stigmata of chronic liver disease in the first 2 months of life. Rarely, there are clinical signs of diagnostic importance (Table 29.8). If the stools are white or grey, there may be complete cholestasis, strongly pointing to surgical conditions such as biliary atresia. Standard tests of liver function, such as serum bilirubin, alkaline phosphatase, aspartate transaminase, GGT, albumin and prothrombin time, do not help to distinguish between the four main groups of disorders. Serum triglycerides and cholesterol are usually normal in the first 4 months of life but may increase

Table 29.8 Clinical signs of diagnostic importance in conjugated hyperbilirubinaemia

ABNORMAL SIGNS	DISORDERS
Skin lesions, purpura, chorioretinitis, myocarditis	Generalised viral infection
Cataract	Galactosaemia or intrauterine infection, hypoparathyroidism
Multiple congenital anomalies	Trisomy 21, 13 or 18
Cystic mass below the liver	Choledochal cyst
Ascites and bile-stained hernias	Spontaneous perforation of the bile ducts
Systolic murmur, abnormal facies, posterior embryotoxon	Arteriohepatic dysplasia (Alagille syndrome)
Cutaneous haemangiomas	Hepatic haemangioma
Situs inversus with or without polysplenia	Extrahepatic biliary atresia
Optic nerve hypoplasia and/or microphos	Septo-optic dysplasia

thereafter, particularly in infants with bile duct hypoplasia. Serum α -fetoprotein values are physiologically elevated in young babies, especially if born prematurely, but are usually much higher in liver disease, particularly in tyrosinaemia (Lindstedt et al. 1992).

Management (Table 29.9)

The first priority on admission to hospital is to identify the causes and complications for which urgent treatment is required. These are septicaemia, urinary tract infection, toxoplasmosis, syphilis, malaria, herpes simplex and metabolic disorders like galactosaemia and fructosaemia. The most dangerous complication is spontaneous haemorrhage due to vitamin K deficiency. Such haemorrhage may well be intracranial. The initial investigations must include prothrombin time, full blood count, blood cultures, urine culture and urine analysis for non-glucose-reducing substances. Galactose and fructose must be excluded from the diet until it is shown that there is no metabolic abnormality primarily affecting their metabolism (Henriksen et al. 1981). After these tests, diagnostic investigations such as α_1 -antitrypsin (α_1 AT) phenotyping and galactose-1-phosphate uridyl transferase activity in red cells should be carried out. If the baby has received a blood transfusion, the parents should be investigated for a possible heterozygote status.

If septicaemia is suspected, broad-spectrum antibiotics and aciclovir must be given. Even if septicaemia is confirmed, there may still be a serious underlying disease, such as galactosaemia, haemophagocytic lymphohistiocytosis (HLH), tyrosinaemia type 1, α_1 ATD or biliary atresia. The finding of non-glucose-reducing substances in the urine does not necessarily indicate galactosaemia, as they may occur in normal babies in the first 2 weeks of life and are common in all forms of liver damage due to secondary proximal tubular damage (Henriksen et al. 1981). Conversely, the absence of non-glucose-reducing substances does not exclude galactosaemia, as very ill babies may feed poorly or vomit. If the prothrombin time is found to be prolonged, vitamin K (1 mg intravenously) should be given immediately and, if bleeding is still occurring or the coagulation times are still significantly prolonged, fresh-frozen plasma

Table 29.9 Investigations in conjugated hyperbilirubinaemia

Immediate investigations in all cases

Bacterial culture of blood and urine
Urine microscopy and analysis for reducing substances
Prothrombin time
Full blood count and reticulocyte count
Blood sugar, creatinine and urea
Serum sodium, potassium, bicarbonate and calcium
Blood group and cross-match

Investigations when full laboratory service is available

Biochemical tests of liver function, including split bilirubin and gamma-glutamyl transpeptidase
IgM/IgG to *Toxoplasma*, *Listeria*, cytomegalovirus, herpes virus, rubella, hepatitis A and C, HIV and syphilis serology
Hepatitis B surface antigen
 α_1 -antitrypsin phenotype or genotype
Red blood cell galactose-1-phosphate uridyl transferase
Sweat electrolytes and immunoreactive trypsin
Serum and urine amino acids
Serum lactate and pyruvate
Mass spectrometry for plasma or urine bile acids
Urine succinyl acetone and organic acids
Direct Coombs' test (if appropriate)
Thyroxine, TSH, cortisol
Chest X-ray/echocardiogram for cardiac lesions
Wrist X-ray for rickets
In the presence of ascites: tap for cytology, biochemical testing and culture
Ultrasound of liver to detect focal lesions and dilated bile ducts
Radionuclide scan (methyl-brom-iminodiacetic acid) scan following phenobarbital (in selected cases)

Tissue diagnosis

Percutaneous liver biopsy
Skin biopsy for fibroblast culture and enzyme analysis (in selected cases)
Bone marrow aspirate for Niemann–Pick disease
Laparotomy, intraoperative cholangiography

Ig, immunoglobulin; HIV, human immunodeficiency virus; TSH, thyroid-stimulating hormone.

infused or exchange transfusion performed. The next priority is to identify those babies who require surgical correction of bile duct obstruction (Table 29.10). Ultrasound examination should be undertaken to exclude a choledochal cyst or focal intrahepatic lesions.

In all infants, infective (Table 29.11), metabolic (Table 29.12) and endocrine (Table 29.13) causes of liver damage affecting this age group must be excluded. With regard to infective conditions, it must be remembered that cytomegalovirus (CMV), rubella and hepatitis B virus have been found to occur in all types of hepatobiliary disease (Henriksen et al. 1981). Seropositivity for these viruses should not preclude investigation of other causes of liver damage. Galactosaemia, fructosaemia and tyrosinaemia must be diagnosed promptly because dietary intervention in the first two conditions and treatment with 2-(2-nitro-4-trifluoro-methyl-benzoyl)-1-3-cyclohexanedione (NTBC) in the last (Lindstedt et al. 1992), need to be instituted urgently to avoid severe deterioration. α_1 ATD, cystic

Table 29.10 Surgically correctable disorders causing bile duct obstruction

Extrahepatic biliary atresia
 Choledochal cyst
 Spontaneous perforation of the bile ducts
 Duodenal and low bile duct atresia
 Gallstones
 Haemangiomas
 Extrinsic compression
 Bile plugs in extrahepatic bile ducts

Table 29.11 Infections associated with conjugated hyperbilirubinaemia (see Ch. 40 part 2)

Cytomegalovirus
 Rubella virus
 Hepatitis A
 Hepatitis B
 Hepatitis C
 Non-A–C hepatitis
 Herpes simplex virus 1 and 2
 Coxsackie A9, B
 Echovirus 9, 11, 14, 19
 Adenovirus
 Reovirus type 3
 Epstein–Barr virus
 Varicella-zoster virus
 Psittacosis
 Bacterial infections
 Listeria
Treponema pallidum
Toxoplasma gondii
 Malaria
 Tuberculosis
 HIV

HIV, human immunodeficiency virus.

Table 29.12 Inherited metabolic disorders associated with hepatitis syndrome in infancy (see Ch. 35 part 3)

Galactosaemia
 Fructosaemia
 Tyrosinaemia
 α_1 -antitrypsin deficiency
 Progressive familial intrahepatic cholestasis
 Mitochondrial cytopathies
 Cystic fibrosis
 Niemann–Pick type C
 Gaucher disease
 Wolman disease
 Zellweger syndrome
 Infantile polycystic disease
 Haemophagocytic lymphohistiocytosis
 Neonatal iron storage disease (perinatal haemochromatosis)
 Carbohydrate glycoprotein deficiency
 Defects in synthesis of primary bile acids

Table 29.13 Endocrine disorders associated with hepatitis syndrome in infancy (see Ch. 35 part 2)

Hypopituitarism
 Diabetes insipidus
 Hypoadrenalism
 Hypothyroidism
 Hypoparathyroidism

fibrosis and Niemann–Pick disease type C should also be sought in all infants because these are relatively common genetic conditions, presently lacking effective treatment but for which antenatal diagnosis is possible. α_1 ATD must be excluded in all cases by determining the α_1 AT phenotype, rather than by means of the serum α_1 AT concentration, which can be within the normal range in the presence of hepatitis or infection, as α_1 AT is an acute-phase reactant (Sifers et al. 1992). This is perhaps the most important investigation in distinguishing severe hepatitis with complete cholestasis from biliary atresia, as the liver disease associated with homozygous PiZ phenotype α_1 ATD (see later) has many clinical and pathological similarities to biliary atresia (Psacharopoulos et al. 1983; Dick and Mowat 1985; Hadzic et al. 2005). Investigation for rarer metabolic diseases should be performed only if suggested by the family history or findings on percutaneous liver biopsy. The frequency with which infective, genetic, pharmacological and toxic causes of hyperbilirubinaemia or structural biliary abnormalities can be identified depends not only on their prevalence in the local community, but also on referral patterns and the sophistication of investigation facilities (Vara and Dhawan 2007).

Figure 29.14 summarises the aetiology of liver disease in infants referred to our tertiary referral centre for management of liver disease during an observation period of 13 years (Vara and Dhawan 2007). Despite improvement of diagnostic tests and discovery of new pathological conditions, such as progressive familial intrahepatic cholestasis syndromes or mitochondrial cytopathies (Thompson and Jansen 2000; Gillis and Kaye 2002), 40% remain undiagnosed.

Identifying bile duct obstruction

Observation of stool colour is vital. Because of photosensitivity of bile pigments in the stool, all stools passed should be saved in the dark (e.g. in a black bag or in a container) and examined for yellow or green pigment; if absent, cholestasis is complete and biliary atresia must be excluded (Fig. 29.15). Referral to a specialist centre is essential (McClement et al. 1985; Mieli-Vergani et al. 1989; McKiernan et al. 2000). A skilfully interpreted percutaneous liver biopsy performed under local anaesthesia using the Menghini technique is diagnostic in up to 90% of cases. If all portal tracts show increased oedema, fibrosis and bile duct reduplication, this strongly suggests major bile duct disease, of which the most common is biliary atresia. This appearance can also be found in genetic disorders such as PiZ α_1 ATD (Schwarzenberg and Sharp 1990; Hadzic et al. 2005), cystic fibrosis, Alagille syndrome (Deprettere et al. 1987), total parenteral nutrition induced liver injury (Pereira et al. 1981; Quigley et al. 1993) and endocrine disorders associated with septo-optic dysplasia. It also occurs in some infants who will ultimately develop bile duct hypoplasia and in disorders of the intrahepatic bile ducts (Deprettere et al. 1987). All of these disorders can cause complete cholestasis. It is essential that some of the material obtained is snap-frozen in liquid nitrogen or at -80°C for

Fig. 29.14 Final diagnosis in infants with liver disease referred to King's College Hospital Paediatric Liver Centre, London, UK, over a period of 13 years (total number of patients 1625). BA, biliary atresia; α_1 ATD, α_1 -antitrypsin deficiency; PFIC, progressive familial intrahepatic cholestasis; BD, bile duct; PNALD, parenteral nutrition-associated liver disease.

subsequent enzymatic analysis for inherited disorders (Table 29.12) if indicated by the liver histology or other investigations.

A scan with ^{99m}Tc -tagged iminodiacetic acid derivatives, such as methyl-brom-IDA, which have good hepatic uptake and relatively poor renal uptake, can be used in prolonged neonatal cholestasis. Discrimination from intrahepatic cholestasis is enhanced if the infant is pretreated with phenobarbital (5 mg/kg/day for at least 3 days). Repeated imaging up to 24 hours after intravenous injection may be required. Equally effective discrimination may be achieved by computer analysis of distribution between the liver and heart within 10 minutes of intravenous injection (El Tumi et al. 1987). Radionuclide studies, however, are only useful if isotope is demonstrated in the gut, thereby excluding biliary atresia and avoiding an unnecessary and potentially dangerous laparotomy. Absence of excretion in the gut does not equate with biliary atresia. Daily observation of the stool colour and trends in serum bilirubin levels are essential even if patency of the bile ducts is demonstrated. If the stools remain acholic, the liver biopsy should be repeated, and further investigations may be necessary to identify the rare instances of late-onset biliary atresia.

The real difficulty arises if there is no excretion, the biopsy is not indicative of atresia and no genetic or endocrine disorder causing complete cholestasis has been identified. At specialised centres,

endoscopic retrograde cholangiopancreatography (ERCP) is an important diagnostic tool in such ambiguous cases (Wilkinson et al. 1991; Shanmugam et al. 2009). In expert hands ERCP is a safe and feasible procedure, even in small babies (Shanmugam et al. 2009). A study has shown that it has a positive predictive value of 87% and negative predictive value of 100% regarding a diagnosis of biliary atresia (Shanmugam et al. 2009). Unless filling of the intrahepatic ducts can be demonstrated by ERCP, such patients should have a laparotomy. It is essential that this is undertaken by an experienced surgeon who can correctly assess the macroscopical changes in the porta hepatis and, being confident of the diagnosis, proceed to portoenterostomy (McClement et al. 1985; Davenport et al. 2008). Final confirmation of the diagnosis comes from histological examination of the excised biliary remnants, by which time an irreversible operation has been performed. Even with intraoperative cholangiography, extrahepatic ducts which are hypoplastic as a result of severe intrahepatic cholestasis may be considered atretic, leading to an unnecessary destructive operation (Davenport et al. 1997).

Surgically correctable disorders

Biliary atresia

Biliary atresia is the most frequent surgically correctable liver condition in infancy, affecting 1:17 000 liveborns (Livesey et al. 2009). It is unique to early infancy and is characterised by complete obstruction of the bile flow secondary to obliteration or destruction of part or all of the extrahepatic biliary tree. Study of bile duct remnants removed at surgery, and from liver specimens, indicates that biliary atresia arises from a sclerosing inflammatory process affecting previously formed bile ducts (Fig. 29.16) (Gautier and Elliot 1981). Recently, comparative anatomical studies have suggested that, in at least some cases, biliary atresia may be caused by failure of the intrauterine remodelling process at the hepatic hilum, with persistence of fetal bile ducts poorly supported by mesenchyme. As bile flow increases perinatally, bile leakage from these abnormal ducts may trigger an intense inflammatory reaction, with consequent obliteration of the biliary tree (Tan et al. 1994). The extrahepatic ducts are primarily damaged, whereas the intrahepatic bile ducts remain patent in early infancy but then also become affected and obliterated and eventually disappear. Cirrhosis with complications such as portal hypertension may appear at any time

Fig. 29.16 Liver histology demonstrating expansion of the portal tract, bile duct proliferation and cholestasis, suggestive of extrahepatic biliary atresia (haematoxylin and eosin).

from 2 months of age, and death by 2 years of age is usual if the disease is not treated (Francavilla and Mieli-Vergani 2002).

The cause of biliary atresia is unknown. Familial cases are extremely rare and, of 17 cases occurring in twins, in only two instances were both affected (Silveira et al. 1991). At our centre we have seen several twin pregnancies and one triplet pregnancy where only one baby was affected. Human leukocyte antigen (HLA) phenotype appears not to play a role (Donaldson et al. 2002). Up to 25% of infants have minor or major abnormalities outside the biliary system, with a particularly high frequency of abnormalities of the vasculature below the diaphragm. Children with splenic malformations, including polysplenia and asplenia, with or without laterality defects (complete or partial situs inversus) may represent a separate aetiological subgroup – biliary atresia splenic malformation (BASM) syndrome (Davenport et al. 2006). It has also been suggested that the precarious blood supply to the biliary tree may be further jeopardised by such abnormalities. An increased incidence of maternal diabetes mellitus has been associated with the BASM syndrome (Davenport et al. 2006). Another suggested aetiological factor is a long common channel for the pancreatic and biliary ducts as they enter the duodenum, with the suggestion that pancreatic juice may reflux into the biliary system and initiate mucosal damage and subsequent inflammatory response. There have been many suggestions that perinatal infection may initiate biliary atresia, but none of the candidate viruses, e.g. reovirus type 3 (Tyler et al. 1998), has been found to infect atresia patients any more frequently than healthy babies (Brown et al. 1988; Morecki and Glaser 1989; Rauschenfels et al. 2009). Other viruses suggested to be implicated in the aetiology of biliary atresia include CMV (Fishler et al. 1998) and rotavirus (Riepenhoff-Talty et al. 1996; Rauschenfels et al. 2009). The rhesus rotavirus-infected neonatal Balb/c mouse is a widely used experimental model of biliary atresia (Barnes et al. 2009) and it will be interesting to see whether recently introduced routine rotavirus immunisation in some developed countries will affect the incidence of biliary atresia in humans.

A specific problem in the diagnosis of biliary atresia is that, as mentioned above, in most cases it results from an obliterative disorder starting in formed extrahepatic ducts which eventually leads to their destruction (Gautier and Elliot 1981). The extrahepatic and intrahepatic bile ducts may be patent in the first weeks of life, but become atretic later. Thus, in up to 30% of infants with atresia, stools are pigmented in the first weeks after birth, before bile flow is completely obstructed. All too frequently the infant's apparent well-being causes paediatricians and other health workers to dismiss consideration of this disorder in early infancy, when the chances of successful surgery are high (Mieli-Vergani et al. 1989). The longer biliary atresia has been present, the greater the likelihood that the intrahepatic bile ducts will have been obliterated and that portoenterostomy will be less likely to be successful. This is particularly true in BASM syndrome (Davenport et al. 2008). As discussed, it is essential to refer infants with acholic stools to units with experience in the interpretation of the diagnostic investigations outlined above, and in the surgical and postoperative management of biliary atresia (Table 29.14) (McKiernan et al. 2000).

At laparotomy, the surgeon must first confirm that the bile ducts are absent or atretic. This is not a simple task, and narrow but patent bile ducts in infants with intrahepatic disease and complete cholestasis have been removed by experienced surgeons (Markowitz et al. 1983). In 5–10% of babies, the surgeon can identify a patent common bile duct containing bile and in continuity with intrahepatic bile ducts (McClement et al. 1985). In these babies, a biliary–intestinal anastomosis via a long Roux-en-Y loop may allow bile to

Table 29.14 Requirements to improve the management of biliary atresia

All babies jaundiced after 14 days of age should have urine analysis and total and direct serum bilirubin determination
 If conjugated bilirubin >25 micromol/L is present, the baby should be referred to a paediatrician for urgent investigation
 If the stools have no yellow or green pigment, the baby should be referred to a specialist centre to exclude or treat biliary atresia
 'Well baby' clinics should be at 4 rather than 6 weeks of age to identify jaundice sufficiently early to increase the chances of successful treatment

drain satisfactorily. In the majority of patients, however, the proximal common hepatic duct is completely obliterated or absent up to where it enters the liver, and at the porta hepatis it is replaced by fibrous tissue. This tissue is transected flush with the liver and a Roux-en-Y loop of jejunum is anastomosed around the fibrous edges of the transected tissue, forming a portoenterostomy (Kasai procedure). For surgery to be effective, the intrahepatic bile ducts must be patent to the porta hepatis (McClement *et al.* 1985). Modifications of the Kasai procedure undertaken to reduce the risks of cholangitis fail to do so and increase the risks of liver transplantation if this becomes subsequently necessary.

In our centre, babies are started on phenobarbital preoperatively at a dose of 5–7 mg/kg/day to promote bile flow, and a dose of 45 mg/day is used postoperatively as maintenance in our unit (Davenport *et al.* 1997). If the jaundice reappears, the dose could be increased to 60–90 mg/day. Other centres use ursodeoxycholic acid (UDCA: 20–30 mg/kg/day) in an attempt to improve bile flow (Willot *et al.* 2008). With a skilful surgeon, good bile flow with normal serum bilirubin values can be achieved in more than 80% of children operated on by 60 days of age, but in only 20–70% with later surgery (Mieli-Vergani *et al.* 1989; Ohi *et al.* 1990; Davenport *et al.* 1997). If bilirubin returns to normal, a 90% 15-year survival has been reported (Ohi *et al.* 1990), with a good quality of life into the fourth decade (Chiba *et al.* 1992). Up to 11% of children are free of clinical and biochemical signs of liver disease after 10-year follow-up (Hadzic *et al.* 2003). If the bilirubin is not reduced, the rate of progression of cirrhosis is not slowed and survival beyond the second birthday is unusual without further intervention. If bile drainage is partially effective, end-stage chronic liver disease may be delayed to 6 or 7 years of age.

An important postoperative complication is cholangitis. Portal hypertension is present in almost all cases at the time of initial surgery. Approximately 50% of all survivors aged 5 years, even those with normal bilirubin levels, have oesophageal varices, but only 10–15% have gastrointestinal bleeding. For these, variceal banding or injection sclerotherapy is the treatment of choice. In approximately 10% of cases in which the serum bilirubin returns to normal, intrahepatic cholangiopathy progresses and complications of biliary cirrhosis ultimately develop (Nietgen *et al.* 1992). For these patients, and those for whom surgery has not been effective, liver transplantation should be considered (Nagral *et al.* 1997). With 1-year survival rates approaching 90% (Nietgen *et al.* 1992), and 5-year survival rates over 80% (Ozawa *et al.* 1992), liver transplantation is now a standard therapeutic option, but it remains a formidable procedure. The recipient is likely to have one or more life-threatening complications in the perioperative or postoperative period. Life-long immunosuppressive therapy is required, with a high risk of opportunistic and community-acquired infections, requiring close medical and surgical supervision. Most of the survivors have a good quality of life and attend school, although the long-term medical

Fig. 29.17 Endoscopic retrograde cholangiopancreatography demonstrating a non-obstructive saccular dilatation of extrahepatic bile duct, strongly suggestive of a choledochal cyst.

and psychological effects of liver transplantation in childhood are as yet unknown. The supply of donors of suitable size and blood group, even with an increased use of split grafts, where one donor liver is used for two recipients – usually one child and one adult – remains a major limiting factor in liver transplantation. Segmental graft transplant from living relatives has given survival rates of 90% in infants in whom Kasai portoenterostomy had been unsuccessful (Ozawa *et al.* 1992). The precise indications and timing, and the optimal management of some of the intraoperative and postoperative problems, including the control of rejection, remain the subject of ongoing assessment and research. Although an important mode of management for end-stage liver disease, the role of liver transplantation in biliary atresia is complementary to that of portoenterostomy (Davenport *et al.* 1997), except for infants in whom decompensated cirrhosis has developed because of delayed diagnosis.

Choledochal cysts

Choledochal cysts are dilatations of the biliary ducts which can be associated with intermittent biliary obstruction. If uncorrected, they lead to progressive biliary fibrosis and ultimately cirrhosis. In the newborn period, the presentation is indistinguishable from neonatal hepatitis or biliary atresia. They are increasingly diagnosed prenatally on routine ultrasound (Stringer *et al.* 1995; Redkar *et al.* 1998). Children in whom a prenatal diagnosis of choledochal cyst is made should be referred promptly to a specialised paediatric hepatology centre, since this could also be the mode of presentation of biliary atresia (Redkar *et al.* 1998). Cholangitis, rupture, pancreatitis and gallstones are important complications of choledochal cyst which can occur even in early infancy, while chronic cholangitis and carcinoma of the cyst wall may be long-term complications.

A cystic echo-free mass demonstrated in the biliary tree by ultrasound is strong evidence for this diagnosis. The intrahepatic bile ducts may be dilated owing to the distal stasis. The cyst can be diagnosed by magnetic resonance cholangiopancreatography, but often ERCP or percutaneous transhepatic cholangiography is needed (Fig. 29.17). The definitive treatment is surgical removal

with biliary drainage via a Roux-en-Y loop (Howard 1989). With adequate surgery, the long-term prognosis is good (Stringer et al. 1995).

Spontaneous perforation of the bile duct

Spontaneous perforation of the bile duct at the junction of the cystic duct and common hepatic duct occurs when, for some unexplained reason, the common bile duct becomes blocked, usually at its distal end. Affected infants have mild jaundice, failure to gain weight and abdominal distension due to ascites, which classically causes the development of bile-stained hernias. The stools are white or cream in colour and the urine is dark. Paracentesis confirms the presence of bile-stained ascites (Howard et al. 1976).

If operative cholangiography shows free drainage of contrast into the duodenum, the ruptured duct may be sutured, but more commonly it is necessary to establish cholecystojejunostomy drainage via a Roux-en-Y loop. With effective surgery, the prognosis is excellent (Howard et al. 1976). Delay in instituting surgery may lead to severe malnutrition, peritonitis and septicaemia.

Miscellaneous conditions

The remaining surgical conditions listed in Table 29.10 are rare, and are usually dealt with either by flushing out the obstruction with a percutaneous or operative cholangiogram or by a biliary reconstruction.

Paucity of interlobular bile ducts (intrahepatic biliary hypoplasia)

This is a pathological diagnosis in which there is a decrease in the number of interlobular bile ducts seen in the portal tracts. It can be found in many conditions causing hepatitis in infancy. If it occurs with cardiovascular, skeletal and ocular anomalies, it is called Alagille syndrome (syndromic paucity of the intrahepatic bile ducts; arteriohepatic dysplasia) (Alagille et al. 1987) and is inherited in an autosomal dominant fashion with variable expression. The estimated incidence is 1:100 000 live births. It is caused by mutations in the human *Jagged-1* gene on chromosome 20p12 (Rand 1998). However, mutations in this gene can also be present in asymptomatic individuals and in other liver conditions, including biliary atresia (Kohsaka et al. 2002). Typically, there is a long-standing cholestasis causing jaundice, pruritus, hypercholesterolaemia and xanthomas. The severity of the cholestasis varies. Mild cases may have pruritus only. The majority have jaundice from the neonatal period, which in severe cases persists, but in others clears in late childhood or early adult life. The long-term prognosis is uncertain, but some 15% may go on to develop cirrhosis and 5–10% die from liver disease (Lykavieiris et al. 2001). In one series, 25% died from cardiac involvement, classically a peripheral pulmonary stenosis or infection (Alagille et al. 1987). Diagnosis is supported by the finding of the typical facies: deep-set eyes, mild hypertelorism, overhanging forehead, a straight nose which in profile is in the same plane as the forehead, a small pointed chin, posterior embryotoxon (a remnant of an embryonic membrane between iris and cornea, seen by slit lamp) and vertebral arch defects on spinal radiographs (Fig. 29.18). A high serum cholesterol and failure to thrive support the diagnosis (Depretere et al. 1987). The treatment is that of chronic cholestasis, with particular emphasis on adequacy of vitamin D, E, K and A supplements and the control of pruritus (Depretere et al. 1987).

Fig. 29.18 Facial appearances of a baby with Alagille syndrome. (Reproduced from Francavilla and Mieli-Vergani (2002).)

Liver damage associated with parenteral nutrition

Prolonged intravenous nutrition, particularly in early infancy, causes cholestasis and hepatocellular damage, which may progress to cirrhosis if intravenous feeding continues with no enteral intake. Prevalence increases with the degree of prematurity, the duration of intravenous feeding and in the presence of associated medical and surgical conditions. Cholestatic jaundice, defined as a direct-reacting bilirubin concentration of greater than 34 $\mu\text{mol/l}$, occurred in 8.6% of 267 infants receiving intravenous nutrition (Pereira et al. 1981). The incidence was inversely proportional to the gestation, being 13.7% in babies of less than 32 weeks', 5.3% in babies of 32–36 weeks' and 1.4% in babies of greater than 36 weeks' gestation. In each gestational age group, the duration of parenteral therapy in babies with cholestasis was significantly longer than in those who remained free from this complication. The babies with cholestasis also tended to be without oral feeding for longer – 23 days as opposed to 15 days (Pereira et al. 1981). Sepsis, hypoxia, shock, blood transfusion, intra-abdominal surgery and potentially hepatotoxic drugs may aggravate the liver damage.

Pathologically, there is a distinct cholestatic hepatitis, with bilirubinostasis within the hepatocytes, the bile canaliculi and Kupffer cells. These cells also contain marked accumulation of periodic acid–Schiff-positive pigment. The hepatocytes are oedematous and may have increased numbers of nuclei. There is a lobular

disarray with distension of portal tracts by inflammatory cell infiltrate, bile duct proliferation and fibrosis. A fine panlobular sinusoidal or pericellular fibrosis may be noted in up to 50% of cases. Severe fibrosis and cirrhosis may develop if total intravenous feeding cannot be stopped. Acute acalculous cholecystitis, biliary sludge and cholelithiasis are frequent complications. Follow-up biopsies 5–9 months after the height of the illness still show mild hepatocellular cholestasis, lobular disarray with ballooning of hepatocytes and increased fibrosis.

The first clinical indication of hepatic involvement is usually the appearance of conjugated hyperbilirubinaemia. Hepatomegaly may be noted. Biochemical tests of liver function are abnormal. It is important to consider other causes of cholestasis in this age group before concluding that the disorder is due to intravenous nutrition. If total parenteral nutrition (TPN) can be withdrawn, the jaundice settles within 4–6 weeks, although liver function tests may remain abnormal for several months and the liver biopsy changes can persist even longer. Tests of liver function should be carried out at least weekly during intravenous feeding.

The prognosis of TPN-associated jaundice is more serious in children with anatomical anomalies or functional intestinal failure (necrotising enterocolitis, gastrochisis, microcolon), who are TPN-dependent and prone to intermittent septic episodes for longer. They may progress to end-stage chronic liver disease, requiring isolated liver transplantation or combined liver and small bowel transplantation (Muiesan et al. 2000).

Treatment of the liver dysfunction associated with parenteral nutrition aims at improving bile flow with the use of UDCA (20–25 mg/kg/day) or phenobarbital (5 mg/kg/day). The most effective treatment, however, is early reintroduction of total or partial enteral nutrition, if tolerated.

Recently, fish oil-based intravenous lipid emulsion has been shown to reduce the risk of parenteral nutrition-associated liver disease in babies with short bowel syndrome (Puder et al. 2009).

Liver disease associated with α_1 -antitrypsin deficiency

α_1 AT is a glycoprotein synthesised largely in the liver. In vitro and probably in vivo it acts as an inhibitor of inflammatory response. Over 90 different alleles, controlled by a single gene, located on chromosome 14q32.1, have been isolated and identified as protease inhibitors (Pi). The alleles of α_1 AT are inherited in an autosomal co-dominant fashion, the most common phenotype being homozygous PiM. α_1 ATD is among the most common single-gene defects, occurring in about 1:2000–1:7000 newborns of European origin (Lomas et al. 1992; Sifers et al. 1992). Liver disease in children is associated with the homozygous PiZ variant, while PiSZ and homozygous PiS phenotypes do not cause liver injury in childhood (Schwarzenberg and Sharp 1990; Hadzic et al. 2005). The plasma deficiency of the glycoprotein is associated with a defect in secretion from the endoplasmic reticulum rather than a defect in the synthesis of the Z polypeptide (Sifers et al. 1992).

The clinical features associated with the deficiency state are very variable, with some having no overt disease, up to 20% developing liver disease of variable severity and up to 60% developing emphysema (Sveger and Eriksson 1995; Francavilla et al. 2000). Cigarette smoking is closely associated with the development of emphysema, but the cause of the liver disease is still not fully elucidated (Schwarzenberg and Sharp 1990; Lomas et al. 1992).

The putative pathogenic mechanism for the liver disease in homozygous PiZ α_1 AT is abnormal 'loop sheet' polymerisation of the mutant α_1 AT protein, leading to abnormal folding and inefficient export from the rough endoplasmic reticulum of the

hepatocytes (Lomas et al. 1992; Sifers et al. 1992). It is likely that genetic and environmental modifiers play a role in the development of liver disease and its severity. Within a family with a PiZ child with liver disease, there is a 70% occurrence of liver disease among homozygous PiZ siblings, but the severity of liver disease is highly variable (Hinds et al. 2006). Suggested additional pathogenic factors include possession of HLA DR3, absence of breastfeeding and male sex, defects in chemotaxis, liver-specific autoimmune reactions, complement activation and the increase in the synthesis of acute-phase reactants during febrile episodes in infection (Lomas et al. 1992). The mechanisms of liver and lung disease in homozygous PiZ α_1 ATD are completely different ('gain of function' as opposed to 'loss of function') (Lomas et al. 1992) and it has been reported that specific single nucleotide polymorphisms in the gene controlling α_1 AT synthesis are likely to be associated with liver injury (Chappell et al. 2008).

Although over 50% of infants with the deficiency state have abnormal biochemical tests of liver function, and these remain abnormal in over 30% throughout the first 12 years of life, only 10–15% develop symptomatic liver disease (Sveger and Eriksson 1995). In 90% of deficient children the liver involvement takes the form of a conjugated hyperbilirubinaemia with hepatosplenomegaly and disturbed biochemical tests of liver function presenting in the first 4 months of life (Psacharopoulos et al. 1983; Francavilla et al. 2000). In 10% of these infants a serious bleeding diathesis due to vitamin K malabsorption is an important component of their illness, potentially leading to intracranial bleeding and permanent neurological abnormality; 1–2% present in later childhood or adult life with cirrhosis with no history of prior jaundice in infancy (Psacharopoulos et al. 1983). Emphysema usually has its onset in early adult life.

The identification of liver disease associated with α_1 ATD in the individual baby is important for diagnostic, genetic and prognostic reasons. Such babies could be considered on clinical, biochemical and histological evidence to have extrahepatic biliary atresia and be subjected to the risks of unnecessary laparotomy. Infants with liver disease associated with α_1 ATD have a significantly worse prognosis than those with hepatitis of unknown cause. In an epidemiological study in south-east England, seven cases of hepatitis in infants were associated with α_1 ATD (Dick and Mowat 1985). By 3 years of age, four had died of cirrhosis, and cirrhosis was present in one of two reviewed at 10 years of age. In contrast, only two of 28 with idiopathic hepatitis in this study died, and none had cirrhosis at 10 years (Dick and Mowat 1985). Our experience with 82 children with the PiZ phenotype and liver disease was that approximately 25% died of cirrhosis by adolescence, a further 25% had histologically proven cirrhosis, 25% had persisting liver disease with possible cirrhosis and 25% apparently recovered from liver disease showing no clinical or biochemical abnormality (Psacharopoulos et al. 1983).

The prognosis of liver disease associated with homozygous PiZ α_1 ATD is correlated with the presence of fibrosis and the severity and duration of the acute hepatitis in early infancy (Francavilla et al. 2000). In the individual baby, the liver biopsy is the most helpful guide to prognosis. In those who die or have persistent hepatic abnormality, there is a marked increase in portal tract oedema and fibrosis in the first 6 months of life (Francavilla et al. 2000). Unfortunately, there is no specific treatment for this form of liver disease, apart from liver transplantation.

Patients with α_1 ATD may have renal involvement with a variety of glomerulonephropathies (Strife et al. 1983). Renal involvement may cause haematuria and/or proteinuria and contribute to hypoalbuminaemia. Subclinical renal complications may manifest as arterial hypertension after liver transplantation.

Reliable methods of genotyping from chorionic villus sampling at 8–10 weeks of gestation are available. Genetic counselling is difficult because of the varying severity of the clinical associations and difficulties in predicting the prognosis (Hinds et al. 2006). Affected families should be carefully counselled and offered the option of sibling testing and prenatal diagnosis for future pregnancies.

Cryptogenic (idiopathic) hepatitis in infancy

Despite an increasing number of specific disorders associated with hepatitis syndrome in infancy, in a high proportion of children the cause still remains unidentified (Fig. 29.14). These children are often born after an abnormal pregnancy and sometimes have a low birthweight. Frequently, they come to medical attention for complications of prematurity or intrauterine growth retardation, and subsequently develop evidence of liver disease. Although the liver disease may be severe, the mortality in such cases is usually less than 15% and long-term hepatic problems occur in less than 10%. The histological features are often non-specific, with portal and lobular inflammation, giant-cell transformation of hepatocytes and variable degree of cholestasis. The indicators of poor prognosis are severe cholestasis with proliferation and/or damage of the intralobular bile ducts and presence of fibrosis, cholangiography showing sclerosing cholangitis (Amedee-Manesme et al. 1987), family history of liver disease in childhood, or consanguinity (Deutsch et al. 1985; Baker et al. 1993), and normal serum GGT in the presence of abnormality of other liver function tests indicating persistent liver disease (Maggiore et al. 1987). This last finding suggests either a primary abnormality of bile acid formation, which must be promptly excluded, as treatment with oral primary bile salts reverses liver damage (Clayton et al. 1995; Subramaniam et al. 2010), or a progressive familial intrahepatic cholestatic (PFIC) syndrome (Thompson and Jansen 2000) due to FIC1 disease (see below; Carlton et al. 1995), or bile salt export pump (BSEP) deficiency (see below), which typically present as non-specific neonatal hepatitis with normal or low GGT (Strautnieks et al. 1997). In this context it is important to remember that the normal values for serum GGT in premature infants, neonates and infants younger than 6 months are severalfold higher than in older children and adults (Cabrera-Abreu and Green 2002).

Progressive familial intrahepatic cholestasis syndromes

Over the last decade, different types of PFIC syndromes, associated with a low or a high GGT phenotype, have been characterised (Thompson and Jansen 2000). These autosomal recessive conditions can present in infancy with prolonged conjugated jaundice (Odievre et al. 1981). GGT in the liver is normally bound to the canalicular membrane and to the cholangiocyte biliary epithelium. Under cholestatic conditions, the detergent effect of the bile acids liberates GGT from the membrane. When this is combined with a poor bile flow, GGT leaks back into the circulation, where elevated levels can be detected. In the absence of bile acids in the bile, even when there is poor bile flow, GGT is not released and the serum levels remain normal. Therefore, in the presence of cholestasis, a normal serum level of GGT correlates very well with low levels of biliary bile acids. These patients usually have low biliary but high serum levels of bile acids, in the absence of a defect in bile acid synthesis.

The original patients described with this phenotype were amongst the Old Order Amish in Pennsylvania, USA (Clayton et al. 1969). One of the original families was called Byler, and this condition has become widely known as Byler disease. Byler disease, or FIC1, represents approximately one-third of the patients with low-GGT

PFIC and maps to chromosome 18 (Carlton et al. 1995). These patients may present with neonatal hepatitis of variable severity. The *FIC1* gene is widely expressed, with only relatively low-level expression in the liver. Thus, some patients with FIC1 disease have extrahepatic manifestations. Expression of *FIC1* is particularly high in the small intestine and pancreas. FIC1 patients may have pancreatitis and many have significant malabsorption, which is not improved by liver transplantation. A proportion of them will have abnormal sweat test, renal tubular dysfunction and conductive deafness.

A further third of patients with low-GGT PFIC have an isolated defect in bile acid transport due to deficiency of the BSEP. The condition maps to chromosome 2 and is due to mutations of the *ABCB11* gene (Strautnieks et al. 1997). These patients mostly present in the first few months of life with a mild neonatal hepatitis. Histologically, the features cannot be discriminated from 'idiopathic' giant-cell hepatitis, which typically has a good prognosis. Immunohistochemically, absence of expression of BSEP and GGT staining can be demonstrated. The disease progresses and pruritus usually becomes a prominent problem towards the end of the first year. The rate of progression is variable, resulting in end-stage liver disease between 2 and 10 years of age, or possibly even later. No treatment apart from transplantation has been shown to be of benefit, and it is particularly noteworthy that these patients appear to be incapable of excreting UDCA (Jansen et al. 1999). Treatment with modest doses of UDCA, however, may have a beneficial effect by further suppressing endogenous bile acid production. As expression of the gene appears to be entirely limited to the liver, liver transplantation is generally an excellent treatment for BSEP deficiency, but there have now been reports of disease recurrence mediated by alloantibody – anti BSEP – formation in patients homozygous for the deficiency after exposure to the BSEP present in the donor liver (Jara et al. 2009; Keitel et al. 2009).

The genetic basis of the remaining third of the low-GGT PFIC spectrum has not yet been clarified.

A form of high-GGT PFIC is associated with multidrug resistance protein (MDR) 3 deficiency, due to mutations of the *ABCB4* gene (de Vree et al. 1998). It is believed that the MDR3 gene product plays a critical role in the flipping of phosphatidyl choline, the major lipid component of human bile, from the inner to the outer leaflet of the canalicular membrane. A defect in phosphatidylcholine excretion is likely to result in the production of highly detergent bile, which can cause considerable tissue damage. Indeed, children with MDR3 deficiency have low phospholipids in the bile and marked portal inflammation and bile duct proliferation in the liver biopsies (de Vree et al. 1998). Two recently described additional clinical manifestations of MDR3 deficiency are cholestasis of pregnancy and cholelithiasis syndrome, characterised by cholesterol gallstones and intrahepatic microlithiasis (Sundaram and Sokol 2007). Some patients, particularly those who have some residual protein function, show a clinical response to UDCA, which reduces the hydrophobicity of the bile. Preliminary data from a murine model show that transplanted hepatocytes are capable of ameliorating the phenotype, suggesting that such transport defects in humans are good candidates for hepatocyte transplantation or gene therapy.

Neonatal haemochromatosis

Neonatal haemochromatosis (NH), or neonatal iron storage disorder, is a rare and often fatal disorder which causes either death in utero or acute liver failure in the neonatal period. The pathogenesis is uncertain. It may represent a single phenotypic expression of different aetiologies (Collins and Goldfischer 1990). NH has been

observed in siblings and it has been suggested to have an autosomal recessive mode of inheritance (Kelly et al. 2001). However, we (Rodrigues et al. 2005) and others (Verloes et al. 1996) have observed NH in neonates conceived by different fathers, suggesting a specific role for maternal factors, possibly mitochondrial (Verloes et al. 1996) or related to pregnancy, including autoimmune reactions or positive systemic lupus erythematosus serology occasionally observed in mothers of affected children (Knisely 1992; Rodrigues et al. 2005). Often the pregnancy is complicated by oligohydramnios and/or megaplacenta. Histologically, the condition is characterised by intense deposition of stainable iron in the liver, hepatocellular necrosis and diffuse hepatic fibrosis with nodular regeneration. Other organs are also typically iron-overloaded, including the pancreas, heart, thyroid and salivary glands, with a characteristic sparing of the reticuloendothelial system (Knisely 1992). Serum ferritin is usually elevated, but its levels do not allow differentiation of neonatal liver failure due to haemochromatosis from that due to other causes (Lee et al. 2001). The diagnosis should be confirmed by lip biopsy to demonstrate stainable iron in the salivary glands (Knisely 1992), although false-positive and false-negative results have been seen (personal observation).

Severe NH, if untreated, is usually fatal. The efficacy of antioxidant-chelating treatment is controversial. After reports of successful use of the cocktail including prostaglandin E₁, selenium, desferrioxamine, *N*-acetyl-cysteine and vitamin E (Shamieh et al. 1993; Roberts et al. 1999; Rodrigues et al. 2005), further reports have failed to show its beneficial effects (Sigurdsson et al. 1998). The treatment was largely ineffective in our own series of 19 severe cases (Rodrigues et al. 2005). Recently, it has been suggested that immune therapy with exchange transfusion and intravenous immunoglobulin may improve the outcome and reduce the need for liver transplantation in patients with NH (Rand et al. 2009). Liver transplantation is at the moment the only procedure able to divert the natural course of the disease. Liver transplantation therefore remains the only real therapeutic option in the presence of severe liver failure (Bonatti et al. 1997).

Prevention of NH is important. The recurrence of NH is high in subsequent pregnancies. Although placental abnormalities have been described in NH, they are not sufficiently specific for antenatal diagnosis. High-dose intravenous immunoglobulin therapy during gestation, on the assumption that the condition may be due to some immune dysregulation, though not preventing NH, dramatically reduces its severity (Whittington and Kelly 2008).

Haemophagocytic lymphohistiocytosis

A primary (familial) form of HLH is an established, but probably still underdiagnosed, cause of liver and multiorgan failure in early infancy. It is thought that an underlying defect in function of cytotoxic/natural killer (NK) lymphocytes, linked to perforin deficiency in about one-third of patients, is responsible for an uninhibited response of the immune system to infection (Kogawa et al. 2002). Perforin is pivotal for translocation of granzyme B from cytotoxic cells into invading microorganisms in order to initiate apoptosis. Primary HLH due to perforin deficiency has an autosomal recessive inheritance and mutations have been mapped to 10q22 (Stepp et al. 1999). Also, at least three additional genetic loci encoding proteins involved in activation of cytotoxic/NK lymphocytes, Munc 13-4 (*UNC13D*), syntaxin-11 (*STX11*) and Munc 18-2 (*STXB2*), have been described (Zur Stadt et al. 2006), with possible phenotypical differences resulting in early-onset or delayed clinical presentations of HLH (Ohadi et al. 1999; Côté et al. 2009). Secondary forms of HLH are often infection-driven, but typically present at a later age and may have a better prognosis.

Clinically, the condition presents acutely with fever, hepatosplenomegaly, pancytopenia, skin rash, and renal and respiratory failure. Laboratory investigations demonstrate hypertriglyceridaemia, hypofibrinogenaemia and hyperferritinaemia. The affected babies become seriously ill over a matter of hours, often requiring assisted ventilation, inotropes and renal support. The diagnosis is confirmed by cytological demonstration of haemophagocytosis in the bone marrow, ascitic fluid or cerebrospinal fluid. Severe coagulopathy often precludes liver biopsy or lumbar puncture. Despite heroic supportive measures, the mortality in the presence of liver failure is more than 90%. Cytotoxic treatment with etoposide or lymphocyte ablation and ciclosporin A has been suggested for milder forms (Hirst et al. 1994). If remission is achieved, the condition can be corrected by stem-cell transplantation (Jabado et al. 1997). There is some early anecdotal evidence that anticytokine treatment (anti-interleukin-2 and antitumour necrosis factor antibodies) could be used as a temporising treatment in severely affected patients with HLH (Verbsky and Grossman 2006).

Mitochondrial cytopathies

An increasing number of infants with hypoglycaemia, sepsis, biochemical signs of liver failure and lactic acidosis are diagnosed with various mitochondrial disorders. These include respiratory chain complex (I–V) deficiency, mitochondrial DNA depletion syndrome (Alpers syndrome), Pearson marrow–pancreas syndrome and primary fatty acid oxidation defects. Most of them do not follow a mendelian mode of inheritance since mitochondrial DNA is inherited maternally and does not recombine. More than 90% of mitochondrial cytopathies are caused by mutations in nuclear genes, only a few of which have been identified (Gillis and Kaye 2002).

Multiorgan involvement is often present since mitochondria provide energy for intracellular processes of oxidative phosphorylation throughout the body. The clinical suspicion of a mitochondrial disorder should be raised in the presence of hypoglycaemia, feeding difficulties, multiorgan and liver failure, neurological impairment, pancreatic insufficiency and failure to thrive. These children are usually not dysmorphic. Elevated serum and cerebrospinal fluid lactate are frequently detected. Magnetic resonance imaging or computed tomography imaging of the head could reveal various anatomical and myelinisation defects (Ch. 40.6). Treatment is of limited help and includes prevention of hypoglycaemia, ubiquinone (coenzyme Q10), thiamine, riboflavine and dichloroacetate. The major management difficulty is consideration for liver transplantation of those children who present with liver failure but have not developed, as yet, signs of neurological impairment or respiratory failure. Whether or not these children should be offered transplantation in view of the possibility of later neurological or respiratory complications is still under debate (Dubern et al. 2001). Recent introduction of rapid testing for the commonest mutations in the DNA polymerase-gamma (*POLG*) gene, responsible for a considerable number of cases of acute liver failure in infancy, including those following exposure to the antiepileptic drug sodium valproate, could assist in the appropriate clinical selection of candidates likely to benefit long term from liver transplantation (Blok et al. 2009).

Management of disorders causing hepatitis syndrome in infancy

The essence of management is to define the site of the main pathological involvement and to identify any associated disorder,

particularly those for which there is specific therapy. Infections must be treated with appropriate anti-infective agents. Fructose and galactose are omitted from the diet until fructosaemia and galactosaemia have been excluded by specific tests. Fat-soluble vitamin deficiencies must be prevented by oral or parenteral supplements (Francavilla and Mieli-Vergani 2002). The exact vitamin requirements depend on the degree of malabsorption and metabolic demands. It is mandatory to monitor the prothrombin time (vitamin K), serum calcium, phosphate and wrist X-rays, together with serum vitamin D, E and A concentrations, to assess adequacy of supplementation. Vitamin K deficiency is an immediate risk of bleeding and a parenteral dose of vitamin K (3–5 mg) is recommended at the time of initial referral of any baby with suspected liver disease, followed by oral supplementation (1 mg/day).

If cholestasis persists for more than 3 months, laboratory or radiological signs of vitamin D deficiency are likely to appear, with pathological evidence of vitamin E deficiency occurring after 5 months. Clinical evidence of vitamin A deficiency develops after some years, but biochemical evidence may be present earlier (Amedee-Manesme et al. 1988). Oral supplements are given in doses of three to five times normal requirements if cholestasis is incomplete. In complete cholestasis, doses of vitamin K 1 mg orally per day, vitamin D 50 000 units intramuscularly at 4-weekly intervals and vitamin A 5000 units intramuscularly at 4-weekly intervals will usually prevent laboratory evidence of deficiency. Vitamin E parenterally in a dose of 10 mg/kg at 2-weekly intervals is required to maintain the serum vitamin E level (Francavilla and Mieli-Vergani 2002). In infants with failure to thrive, dietary supplements of carbohydrate polymers and medium-chain triglycerides (if defects of fat oxidation have been excluded) are required.

Colestyramine (cholestyramine) with or without phenobarbital, UDCA or rifampicin may be required for pruritus. There is no medical treatment that influences the progression of idiopathic disorders.

Inherited disorders of bilirubin metabolism

Gilbert syndrome

A chronic, mild, variable unconjugated hyperbilirubinaemia, with serum bilirubin levels around 34–85 µmol/l (2–5 mg/dl), in the absence of significant haemolysis or abnormality of liver function, is the characteristic feature of this condition. The pathogenesis is undetermined. Impaired hepatic uptake of bilirubin, deficient uridine diphosphate glucuronyl transferase (UDPGT) activity and a mild excretory defect have been suggested (Monaghan et al. 1996). An abnormality of the promoter region of the *UDPGT1* gene, inherited in an autosomal recessive fashion, has been demonstrated

(Bosma et al. 1995). The frequency of the abnormal promoter among the normal population is 40%. Because clinically manifested Gilbert syndrome occurs in 3–10% of the population, other factors, such as an increased bilirubin production, must be present to bring this disease to expression. The diagnosis is rarely made with confidence before 10 years of age and is based on exclusion of other causes of unconjugated hyperbilirubinaemia. Treatment is unnecessary. Gilbert syndrome may aggravate physiologic hyperbilirubinaemia in the newborn (Bancroft et al. 1998).

Crigler–Najjar disease

This rare disorder is characterised by significant unconjugated hyperbilirubinaemia from birth. Crigler–Najjar disease type 1 results from a complete deficiency of UDPGT, and type 2 from a partial deficiency. In Crigler–Najjar disease type 1, serum bilirubin values are in excess of 350 µmol/l and the bile contains only traces of bilirubin conjugates. Crigler–Najjar disease type 2 is clinically less severe, with serum bilirubin values not exceeding 350 µmol/l. The bile of these patients contains bilirubin mono- and diglucuronides in low concentration. Genetically, both diseases result from mutations of the *UDPGT1* gene (Ritter et al. 1992; Aono et al. 1993). Both Crigler–Najjar type 1 and type 2 are inherited in an autosomal recessive fashion (Kadakol et al. 2000). The diagnosis is suspected on the basis of the clinical features and needs to be confirmed by mutation analysis, assessing bilirubin conjugates in the bile collected at endoscopy, or by measuring UDPGT activity in a percutaneous liver biopsy specimen. In Crigler–Najjar type 2, serum bilirubin levels decrease by at least 30% with phenobarbital treatment. Patients with Crigler–Najjar type 1 are at risk of developing neurological damage and kernicterus throughout their life, but particularly in early infancy. Most patients require exchange transfusions to control hyperbilirubinaemia in the newborn period, and thereafter require continuous phototherapy of sufficient intensity to keep the serum bilirubin below 300 µmol/l. This is most conveniently achieved by sleeping undressed for up to 12–15 hours under a specially built phototherapy device incorporating as many as 32 phototherapy tubes (Yohannan et al. 1983). Oral colestyramine may reduce the phototherapy requirement by binding bilirubin in the gut. After 4 years of age, phototherapy gradually becomes less effective and liver transplantation becomes necessary to prevent kernicterus (Pett and Mowat 1987). Auxiliary liver transplant, where the left lateral segment of the recipient is removed and substituted with the donor's left lateral segment, has proved successful in correcting the enzymatic defect. Hepatocyte transplantation is a therapeutic option which may offer non-surgical correction of the enzymatic defect, but a sustained medium- to long-term effect has not been achieved as yet (Fox et al. 1998).

Part 3: Gastrointestinal disorders

Simon Newell

Structure and function of the developing gastrointestinal tract

Neonatal gastrointestinal function

Digestion and absorption

This is dealt with in detail in [Chapter 16 part 1](#).

Motility

The ontogeny of motility lags behind digestive and absorptive function ([Fig. 29.19](#)). Disordered motor function presents clinically as 'poor tolerance of feeds'. Symptoms include vomiting, high gastric residual volume, bile staining of the gastric aspirate, abdominal distension and reduced stool frequency.

The oesophagus has two complementary functions: swallowing and the prevention of gastro-oesophageal reflux. Nutritive swallowing is seldom present in the infant of less than 34 weeks' gestation, and 75% of healthy preterm infants require tube feeding until this postconceptional age. The fetus begins to swallow liquor at around 16 weeks' gestation. Initially small volumes are swallowed, increasing to around 500 ml/day by term. Fetal swallowing is an important mechanism in the regulation of liquor volume, and reduced swallowing explains the polyhydramnios seen in oesophageal atresia or in fetuses with neuromuscular conditions ([Pritchard 1966](#)).

In the term infant, the complex mechanism of swallowing with movement of the bolus of milk into the stomach, protection of the airway, inhibition of respiration and appropriate relaxation of the

oesophageal sphincter and gastric fundus is achieved within a day or two of birth.

The mature suck–swallow pattern has bursts of sucks at a rate of 2 per second, with oesophageal transit on a few occasions during each burst ([Papaila et al. 1989](#)). In the preterm infant, uncoordinated motor activity explains the problems with milk tolerance and gastro-oesophageal reflux ([Newell et al. 1989](#)).

Gastric emptying is slow in the preterm infant, presenting as failure to tolerate milk feeds. Half emptying time for breast milk

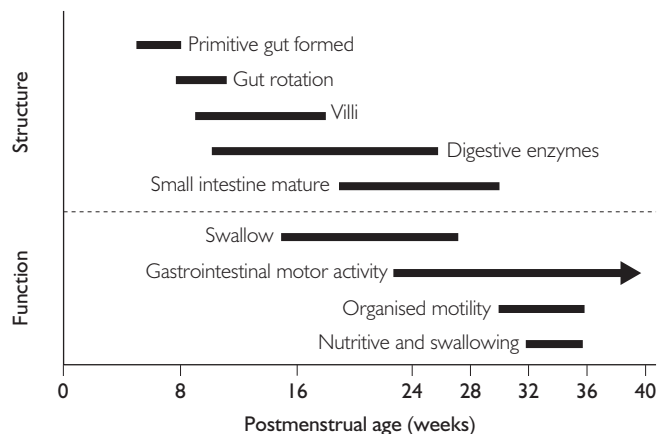

Fig. 29.19 Ontogenic timetable of gut structural and functional development. (Redrawn from [Newell et al. \(1993\)](#).)

Fig. 29.20 Factors affecting gastric emptying. RDS, respiratory distress syndrome. (Redrawn from Newell (1996).)

Fig. 29.21 Time of passage of first stool after birth (Clark 1977; Weaver and Lucas 1990).

has been estimated as 20–40 minutes (Newell et al. 1993; Ewer et al. 1994). Emptying is faster with breast milk than formula. A number of other factors affect gastric emptying (Fig. 29.20). Breast milk fortifier does not affect gastric emptying during the introduction of milk feeds (McClure and Newell 1996), although emptying is slower with full-volume, 3-hourly feeds (Ewer and Yu 1996).

In the preterm infant, propagative small intestinal motility is poorly organised, with short bursts of motor activity before 30 weeks' gestation, which subsequently become coordinated, coincident with the timing of nutritive sucking. Small intestinal motility and tolerance of feeds are enhanced by previous exposure to enteral nutrition (Berseeth and Nurdyke 1993; McClure and Newell 1999).

Total gut transit time varies between 1 and 5 days (McClure and Newell 1999; Berseeth et al. 2003). Passage of stool occurs within 24 hours of birth in 94–98% of healthy term infants. The passage of stools is slower in the preterm infant and frequency is inversely related to gestation (Fig. 29.21) (Clark 1977; Weaver and Lucas 1990). Around half of infants under 28 weeks' gestation have not passed their first stool within the first 3 days.

Barrier function

Mucosal protection is afforded by luminal, mucosal and systemic mechanisms (Table 29.15). Gastric acid, the first-line defence, reduces gastric pH below 4 within hours of birth in all but the most immature infants, in whom this occurs within the first week (Kelly and Newell 1994). Enteral feeds buffer gastric acidity.

Table 29.15 The gastrointestinal barrier: factors that may protect against intestinal pathogens, toxins and antigens

Non-immune

Intraluminal

- Gastric acid
- Motility
- Pancreaticobiliary secretions
- Breast milk factors
 - Lysozyme
 - Lactoferrin
 - Oligosaccharides

Mucosal

- Mucus, bicarbonate and glycocalyx
- Microvillous membrane

Immune

- Secretory IgA
- Cellular immunity (gut-associated lymphoid tissue and milk)
 - Macrophages
 - Lymphocytes
 - Leukocytes
 - Complement

Intact absorption of large molecules occurs across the neonatal gut. Macromolecular absorption is higher in preterm and small-for-gestational-age infants and diminishes over the first months of life. This process of gut closure may occur more rapidly if breast milk is given rather than cow's milk formula.

Signs of gastrointestinal disease

Vomiting

Vomiting is a common sign and assessment should take account of volume, frequency and content of the vomitus and associated symptoms. Effortless regurgitation may represent gastro-oesophageal reflux (see below). Vomiting is often a sign of disease outside the gastrointestinal tract, notably infection (meningitis, pyelonephritis, hepatitis), disease of the central nervous system (intracranial haemorrhage, hydrocephalus), metabolic disorders (galactosaemia, congenital adrenal hyperplasia, thyrotoxicosis) and heart disease (cardiac failure).

Persistent vomiting may indicate obstruction. Upper gastrointestinal obstruction leads to vomiting shortly after birth while incomplete or lower obstruction presents later. Polyhydramnios during pregnancy or the 'mucusy' baby at delivery demands exclusion of oesophageal atresia before a feed is given. Fetal ultrasound reliably detects most cases of diaphragmatic hernia and duodenal atresia but malrotation, upper gut atresia, partial obstruction or web and duplication cysts are less often diagnosed antenatally. Most obstruction occurs distal to the ampulla of Vater, including the vast majority of duodenal atresias. Bile-stained vomiting indicates a surgical problem until proved otherwise. Hernias are an important site of obstruction at all ages.

Vomiting later in the neonatal period is less specific to obstruction. Functional obstruction occurs in necrotising enterocolitis (NEC) and ileus. Luminal obstruction may occur and is seen in meconium ileus, meconium plug syndrome and, rarely,

lactobezoar. In malrotation, initial symptoms may be intermittent. Hirschsprung disease may not present with typical features of abdominal distension and vomiting and this diagnosis should be considered following delayed passage of meconium. Hypertrophic pyloric stenosis is a difficult diagnosis to make when signs begin – we have all been caught out by a preterm infant developing hypertrophic pyloric stenosis in front of our eyes!

Upper gastrointestinal bleeding

The appearance of small amounts of fresh blood or 'coffee grounds' in vomitus is not rare. In most infants a cause is not found and the prognosis is good. Swallowed maternal blood during birth or breastfeeding may lead to haematemesis or melaena. If blood is fresh, differentiation between adult and fetal haemoglobin is helpful.

Gastrointestinal bleeding may mark a bleeding diathesis. Classical haemorrhagic disease of the newborn still occurs if adequate vitamin K prophylaxis is not given. Late vitamin K deficiency bleeding is more common in babies with liver disease. Assessment of coagulation status is imperative if there is significant gastrointestinal bleeding, in order to rule out disseminated intravascular coagulation (DIC) or an inherited bleeding tendency.

Upper gastrointestinal ulceration occurs in the fetus (Bedu et al. 1994), the newborn after perinatal stress (De Boissieu et al. 1994) and babies receiving intensive care (Maki et al. 1993). At endoscopy, an oesophagogastritis of unknown aetiology occurs in a large proportion of infants presenting with haematemesis, frequent regurgitation or poor growth (De Boissieu et al. 1994). Rarely, haematemesis indicates congenital varices, true peptic ulcer, gastric or intestinal volvulus, duplications or haemangioma (Vinton 1994). The administration of dexamethasone or tolazoline may be associated with bleeding or perforation. We routinely use ranitidine as prophylaxis in infants receiving dexamethasone (Kelly and Newell 1994). H₂ blockade or proton pump inhibition is used for stress bleeding and other upper gastrointestinal bleeding (Bedu et al. 1994). Routine inhibition of gastric acid secretion is not recommended, and predisposes to NEC (Guillet et al. 2006).

Rectal bleeding

Rapid intestinal transit may allow upper gastrointestinal bleeding to appear as fresh blood per rectum. A small amount of fresh rectal bleeding is commonly due to an anorectal fissure. This is usually obvious on inspection or can be seen by inserting a lubricated auroscope speculum into the anal canal. A wide variety of intestinal conditions may lead to rectal bleeding, including malrotation, volvulus, intussusception and Hirschsprung disease. Meckel's diverticulum, haemangiomata and bowel telangiectasia most commonly present after the neonatal period (De La Torre et al. 2002). Rectal bleeding may denote NEC, particularly in the preterm baby (see below).

Dietary protein intolerance is an important cause of bleeding and colitis, with blood and mucus per rectum (see below).

Diarrhoea

The immediate and universal consequence of diarrhoea is loss of water and electrolytes. Dehydration may be rapid because of low body mass and the relative importance of colonic water and electrolyte conservation. Infective causes are common and a history of contact and stool culture is important. Loose, abnormal stools may indicate NEC (see below) or even Hirschsprung disease. In

persistent diarrhoea, rare disorders of mucosal function should be considered (see below) which may lead to diarrhoea in utero and polyhydramnios. Pancreatic malabsorption occurs in cystic fibrosis, Schwachman syndrome and pancreatic hypoplasia but does not usually present with diarrhoea in the neonatal period.

Constipation

Delayed passage of meconium may indicate obstruction or Hirschsprung disease. Meconium ileus, with thick, inspissated stools and abdominal distension often associated with palpable faecal masses, is almost pathognomonic of cystic fibrosis (see below). In meconium plug syndrome, symptoms usually resolve after the first passage of meconium. Hypothyroidism, hypercalcaemia, diabetes insipidus and renal tubular acidosis may all present with constipation.

In very-low-birthweight (VLBW) infants, infrequent or delayed passage of meconium or stool may be associated with poor tolerance of feeds, particularly in the preterm infant with intrauterine growth restriction. Suppositories may be helpful in inducing defecation.

Necrotising enterocolitis

Epidemiology

The incidence of NEC lies between one and three cases per 1000 live births. NEC occurs in 2–5% of VLBW infants, and in 1–8% of admissions to neonatal intensive care (Beeby and Jeffrey 1992; Kliegman et al. 1993; Fitzgibbons et al. 2009; Rees et al. 2010). This equates with 500–1500 cases each year in England and Wales. The mortality of NEC was 22% in 1998 (Lucas and Morley 1998), but has now fallen to around 13% (Rees et al. 2010). Most affected infants are preterm, but 12% of infants with NEC are born at term (Fig. 29.22) (Beeby and Jeffrey 1992; Kliegman et al. 1993; Clark and Miller 1996). NEC occurs in 14% of infants under 26 weeks' gestation and in less than 1% after 32 weeks. Mortality ranges from 42% to 16% across a birthweight range of 500–1500 g (Fitzgibbons et al. 2009). The onset of signs is most commonly in the second week (Fig. 29.23). There are no reliable seasonal, sexual or geographical patterns with NEC.

Fig. 29.22 Gestation at diagnosis of necrotising enterocolitis: results of a survey in the UK over a period of 1 year. All cases are shown by the open bars. Cases confirmed at surgery, with gas in the portal tract, or free gas in the abdomen are shaded. (Redrawn from Lucas A. Abbott R in collaboration with the Royal College of Paediatrics and Child Health Research Unit.)

Fig. 29.23 Age at onset of necrotising enterocolitis in 129 cases notified to the Communicable Diseases Surveillance Centre, July 1980 to June 1981. (Redrawn from *Communicable Disease Report* (1982).)

Table 29.16 Risk factors incriminated in the aetiology of necrotising enterocolitis

- Prematurity
- Intrauterine growth restriction
- Abruptio placentae
- Premature rupture of membranes
- Perinatal asphyxia
- Low Apgar score
- Umbilical catheterisation
- Hypoxia and shock
- Hypothermia
- Patent ductus arteriosus
- Non-human milk
- Hypertonic feeds
- Rapid introduction of enteral feeds
- Fluid overload
- Pathogenic bacteria
- Polycythaemia
- Thrombocytosis
- Anaemia
- Exchange transfusion
- Cyanotic congenital heart disease

NEC is a common end point precipitated by a number of different circumstances (Table 29.16). Babies with NEC may be divided broadly into three groups (Beeby and Jeffrey 1992). In the term baby, NEC is almost universally associated with major risk factors for gut ischaemia, principally perinatal asphyxia, and often occurs in the first days. NEC may occur at term in Hirschsprung disease (Beeby and Jeffrey 1992). Preterm infants under 30 weeks' gestation who develop NEC usually have no risk factors other than prematurity. In contrast, preterm infants of 30–36 weeks' gestation have greater evidence of perinatal asphyxia than case controls and a higher rate of intrauterine growth restriction (Beeby and Jeffrey 1992). In most preterm infants, NEC develops in the second or third weeks, after the introduction of enteral feeds (Fig. 29.23) (Communicable Disease Report 1982).

Pathology

NEC may affect any part of the gastrointestinal tract. In babies who come to surgery, or in those who die, the commonest sites of disease are the terminal ileum, caecum and ascending colon. NEC is a transmural disease. The bowel appears purple and discoloured, and is often distended with areas of serosal damage. Pneumatosis, the presence of submucosal and subserosal gas within the bowel wall, is the most characteristic appearance of the gut at laparotomy,

Fig. 29.24 Pathological specimen showing necrotising enterocolitis. Pneumatosis is evident with gas bubbles within the bowel wall.

histologically and radiographically (Fig. 29.24). This gas is largely nitrogen and hydrogen and is produced by gas-forming bacteria.

Histologically the earliest signs are a coagulative necrosis of the mucosa with microthrombus formation, leading to patchy mucosal ulceration, oedema and haemorrhage. In focal intestinal perforation, haemorrhagic necrosis is a feature that distinguishes this condition from classical NEC (Pumberger et al. 2002).

Cytokines have an important role in modulating intestinal inflammation and damage in NEC (Kliegman et al. 1993; Claud 2009). Raised levels of interleukins-1, -3 and -6, tumour necrosis factor- α and platelet-activating factor (PAF) relate to severity of the disease. PAF, the lipid-derived, proinflammatory cytokine, has a central role (Ewer 2002). Human infants with NEC have high levels of PAF and low levels of PAF-acetylhydrolase, an enzyme important in PAF degradation (Kliegman et al. 1993). Enterocyte death is induced by imbalance in the pro- and anti-inflammatory balance with increased proapoptotic protease activity (Jilling et al. 2004; Claud 2009). This understanding moves on rapidly, offering the potential of prophylaxis or novel treatment in the future.

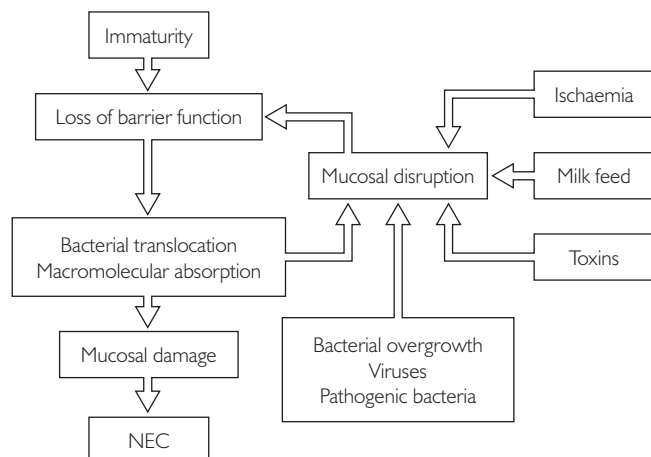

Fig. 29.25 Interaction of the main factors involved in the pathogenesis of necrotising enterocolitis (NEC).

Aetiology

Numerous potential risk factors have been explored (Table 29.16). It is clear that none is in itself necessary or sufficient to produce NEC. The major candidate factors include hypoxia, prematurity and poor mucosal integrity, the bacterial flora and the presence of a metabolic substrate – milk – in the intestinal lumen (Fig. 29.25). These subjects will be discussed individually and have been reviewed extensively (Kliegman et al. 1993; Clark and Miller 1996; Claud 2009).

Gut hypoxia

The pathology of NEC is that of vascular congestion, haemorrhage and ulceration, supporting underlying hypoxic ischaemia. In the term infant with NEC, risk factors for gut hypoxia are almost invariably present. NEC may follow severe generalised hypoxia, maternal cocaine abuse and exchange transfusion (Beeby and Jeffrey 1992; Ozek et al. 2010). In lambs, polycythaemia reduces oxygen delivery to the gut and produces NEC, although the previously reported association in the human is not borne out in more recent literature.

An adverse intrauterine environment leads to chronic fetal hypoxia and intrauterine growth restriction, and diversion of cardiac output away from the gut with reduced blood flow through the superior mesenteric artery.

Studies have shown that absent or reversed end-diastolic flow on fetal Doppler studies predispose to NEC (odds ratio for NEC 2.13 (1.49–3.03)) (Dorling et al. 2005). In such infants reduction of gut blood flow is still evident after birth. The result is the consensus that infants with abnormal fetal Doppler studies, often associated with intrauterine growth restriction, are considered at high risk of NEC. In such fetuses, oligohydramnios and fetal echogenic bowel predict difficulties in the introduction of milk (Ewer et al. 1993). Intrauterine growth restriction is an important risk factor for NEC in infants over 29 weeks' gestation (Beeby and Jeffrey 1992).

The preterm infant is at particular risk of intestinal hypoxia during intensive care. In the animal model, bacterial colonisation and excessive formula feeding do not precipitate NEC unless hypoxia is also present (Caplan et al. 1994). In the newborn, after feeds, intestinal oxygen use is increased but not blood flow, predisposing to tissue hypoxia. Patent ductus arteriosus diminishes superior mesenteric artery blood flow and is more common in infants

Table 29.17 Organisms associated with epidemics of necrotising enterocolitis (Rotbart and Levin 1983; Clark and Miller 1996)

- *Klebsiella* spp.
- Non-pathogenic *Escherichia coli*
- Enterotoxigenic *Escherichia coli*
- *Enterobacter* spp.
- *Clostridium difficile*
- *Clostridium butyricum*
- *Clostridium perfringens*
- *Salmonella* spp.
- *Pseudomonas aeruginosa*
- Rotavirus
- Coronavirus

with NEC (Rowe et al. 1994). Indometacin has long been said to predispose to NEC, although this is not borne out in meta-analysis (Jones et al. 2011). Perhaps the reason for this is that indometacin causes a focal intestinal perforation rather than true NEC; the combination of indometacin and steroids appears to be particularly potent in this regard.

Some of the earliest reports of NEC were in infants after exchange transfusion for rhesus haemolytic disease through an umbilical venous catheter. Umbilical arterial cannulation has been held to reduce gut blood supply and provoke embolisation or thrombus formation, predisposing to NEC. The studies confirming this relationship were all published prior to 1980. Most neonatologists avoid full milk feeds with an umbilical catheter in place, but early or late introduction of small volume feeds with a high or low umbilical artery catheter does not predispose to NEC (Kempley et al. 1993; Davey et al. 1994). The umbilical venous catheter does not predispose to NEC (Raval et al. 1995).

Mucosal integrity

Loss of mucosal integrity disrupts barrier function, allowing macromolecular absorption and bacterial translocation, and interferes with digestion. The preterm gut has an immature microvillous membrane with relative deficiency of mucus and secretory IgA, with increased permeability to small and large molecules (Rouwet et al. 2002). Further mucosal damage increases permeability to microorganisms and toxins. This process may initiate NEC (Clark and Miller 1996; Claud 2009). Antenatal corticosteroid administration induces intestinal maturation, decreases permeability and protects against NEC.

Microbial infection

Most NEC is not infectious. In sporadic disease, the presence of bacteria is probably necessary for NEC to occur but is not sufficient without other risk factors. In epidemic NEC there may be an identified infectious agent (Table 29.17) (Rotbart and Levin 1983; Clark and Miller 1996). Infection with clostridia, which produce a potent toxin, occurs in epidemics and in Hirschsprung's enterocolitis. Infants with NEC during epidemics fare better than infants with sporadic disease, although this may be related to heightened awareness and earlier detection of NEC on the neonatal unit (Clark and Miller 1996).

In sporadic disease, a large variety of microorganisms are associated with the pathogenesis of NEC (Table 29.18) (Communicable Disease Report 1982; Clark and Miller 1996). Positive blood

cultures are found in 10–50% and correlate with isolates from stool or peritoneal fluid (Beeby and Jeffrey 1992; McKeown et al. 1992; Chan et al. 1994). Overall, the microbiological picture is dominated by *Escherichia coli*, *Klebsiella*, *Enterobacter* and coagulase-negative staphylococci. In surgical patients, peritoneal culture shows a wider variety of microorganisms in extremely low-birthweight infants (under 1000 g) than in larger preterm infants (Rowe et al. 1994).

Unhindered proliferation of potentially pathogenic species may occur, promoting bacterial translocation and absorption toxic products, explaining the increased risk of NEC in infants whose mothers were treated with co-amoxiclav after preterm rupture of membranes (Kenyon et al. 2001). Among klebsiellas, rapid carbohydrate fermenters are more pathogenic.

Enteral nutrition

The choice of milk and the management of enteral nutrition are crucial to the prevention of NEC. All studies have demonstrated that most infants with NEC have received milk (Kliegman and Fanaroff 1981; Rowe et al. 1994; Lucas and Morley 1998; Llanos et al. 2002). In unfed infants with NEC, symptoms present early, often following an asphyxial insult (Clark and Miller 1996). Intraluminal milk may simply promote bacterial proliferation or increase bacterial endotoxin production by Gram-negative bacteria (Kliegman et al. 1993). Bacterial action upon unabsorbed nutrients results in gas formation and the production of short-chain fatty acids, which can be toxic to intestinal epithelium. Long-chain fats and undigested casein may contribute to inflammation and injury (Kliegman et al. 1993) and the lipid in milk increases mucosal permeability. Immature patterns of motility and decreased digestive capacity predispose the preterm infant to NEC (Berseth 1994; Newell 2000). In healthy infants who do not develop NEC, milk induces a cellular and humoral inflammatory mucosal reaction with an increase in circulating cytokines (Kliegman et al. 1993).

The method of enteral feedings influences incidence of NEC (Uauy et al. 1991) but prolonged delay of oral feeding is not recommended. The evidence that aggressive enteral feeding with rapid increase in feed volume is causative is more compelling (McKeown et al. 1992), although there is an absence of good randomised controlled trial data (Kennedy et al. 2000). Hyperosmolar feeds, as may occur when multiple additives are given, promote mucosal damage and NEC (Book et al. 1975).

Breast milk protects against NEC (Lucas and Cole 1990; McGuire and Anthony 2003; Meinen-Derr et al. 2009). Infants given breast milk are seven to 10 times less likely to suffer from NEC, a benefit that is attenuated when breast milk is given with formula. Putative important factors in breast milk include immunoglobulins, lysozyme, complement, macrophages, growth factors, PAF-acetylhydrolase (Kliegman et al. 1993) and production of anti-inflammatory cytokines (Dvorak et al. 2003). Prebiotic oligosaccharides in breast milk are bifidogenic, promoting a gut flora which may protect against NEC (Coppa et al. 2006).

Trophic feeding – the use of minimal enteral feeds with parenteral nutrition – does not increase the risk of NEC (McClure and Newell 2000; Bombell and McGuire 2009). Trophic feeding prior to standard milk advancement may protect against NEC (Berseth et al. 2003).

Clinical features

Presentation may vary from insidious deterioration with non-specific signs, lethargy, temperature instability and apnoeic episodes to a rapidly progressive illness with shock, peritonitis and death. In the infant without gastrointestinal symptoms, early recognition of NEC requires a high index of suspicion. The baby's general condition is similar to that seen in sepsis with pallor, skin mottling and often jaundice. Bleeding may be due to DIC. Some infants have initial mild feed intolerance exhibited by increased volume of gastric residuals or emesis and then go on to demonstrate the classic

triad of abdominal distension, bloody, mucousy stools and bile-stained vomit or aspirates. There is little information on the 'normal' gastric residual in a preterm baby, but, in general, residuals of up to 2–3 ml are well tolerated. Clinical experience supports the common practice of careful review of a baby who consistently has more than 50% of feed volume as a 'residual'.

The commonest abdominal sign is distension (Table 29.19). Careful assessment should be made for tenderness: often, distended loops are palpable and an intra-abdominal mass may represent localised perforation. Blue abdominal discoloration suggests disease progression and occasionally the abdominal wall becomes indurated and red, a sign of underlying peritonitis. General assessment of cardiorespiratory function, blood pressure and perfusion is as important as examination of the abdomen.

Focal intestinal perforation is distinguished from NEC by pathology and clinical features. Focal intestinal perforation occurs earlier in life, characteristically in infants of low gestation who are receiving full intensive care, and is associated with blue discoloration of the abdomen (Pumberger et al. 2002).

Investigation

Immediate investigations include haemoglobin, white cell and platelet counts, coagulation studies, urea, electrolytes and albumin and blood gas analysis. The platelet count initially rises, but falls with disease progression and DIC. Blood and fluid losses into the abdomen are often larger than appreciated and abnormalities of perfusion, anaemia and electrolyte balance are common. Metabolic acidosis is usually a marker of shock. Carbon dioxide retention or hypoxia may represent respiratory failure due to apnoea or diaphragmatic splinting and indicates the need for ventilatory support.

Abdominal radiography is mandatory. The bowel appearance varies from a gasless abdomen (Fig. 29.26) to dilated loops of thick-walled gut with fluid levels. The pathognomonic radiographic appearance is pneumatosis intestinalis due to bubbles of gas in the gut wall (Fig. 29.27). In severe disease gas collects within the portal venous system (see below) (Rowe et al. 1994).

Radiological detection of perforation is not easy (Fig. 29.28). Free air may be seen in only two-thirds of infants in whom

Fig. 29.26 Plain abdominal X-ray showing ascites in necrotising enterocolitis.

perforation is present. A lateral horizontal beam shoot-through X-ray may allow easier detection of anterior collection of gas (Fig. 29.29) but, on a supine film, free gas is best seen between the liver and the diaphragm. Free gas in a generally gasless abdomen without pneumatosis favours focal intestinal perforation (Pumberger et al. 2002).

Fig. 29.27 Plain abdominal X-ray showing intraluminal gas (arrows) in necrotising enterocolitis.

Fig. 29.28 Plain abdominal X-ray (anteroposterior supine) in the presence of a perforation: free gas is seen under the diaphragm (arrowed).

Fig. 29.29 Same infant as shown in [Figure 29.28](#), radiographed lying on the left side with a shoot-through horizontal beam film.

Acute-phase proteins (C-reactive protein) are helpful in monitoring progress. Abdominal ultrasound may allow detection of masses or ascites. Contrast studies are avoided during the acute phase and should not be done outside a centre capable of providing immediate surgery.

Differential diagnosis

In most cases, recognition of NEC is not difficult. Other causes of gut ischaemia, including malrotation, volvulus and hernia, should be considered. Isolated rectal bleeding has a differential diagnosis, discussed above. Abdominal distension with regurgitation is common and, although NEC should be considered, it is reasonable to stop oral feeds for a few hours and observe the infant who has no other signs. 'NEC' may be the presenting feature of Hirschsprung disease or cystic fibrosis (Wood et al. 1995).

Treatment

The spectrum of clinical presentations makes it difficult and inappropriate to define a rigid regimen of management. Staging criteria are helpful in tailoring treatment (Bell et al. 1978; Walsh and Kliegman 1986) (Table 29.20).

Medical

The overall aim of treatment is to rest the gut, control infection, restore metabolic equilibrium and, with intensive or high-dependency care, maintain the infant in an optimal condition until the bowel heals. Suspension of enteral feeding means that parenteral nutrition should be provided. Surgery is indicated if intestinal perforation occurs, the infant's general condition deteriorates or intra-abdominal pathology persists beyond a few days.

The major components of medical management are:

- Cessation of enteral feeding.
- Nasogastric drainage with suction to minimise abdominal distension.

- Monitoring of temperature, pulse, respiratory rate, blood pressure, fluid balance.
- Plain abdominal radiography: if symptoms persist, radiographs should be repeated 6–12-hourly on the first day of NEC and while perforation remains likely.
- Peripheral venous access for antibiotics, blood and plasma.
- Blood cultures and septic screen; a lumbar puncture is not usually performed.
- Intravenous antibiotics: a triple-antibiotic regime is commonly used. Gram-negative cover: gentamicin or a third-generation cephalosporin (e.g. ceftazidime), although resistance to the latter is emerging. Gram-positive cover: amoxicillin or vancomycin. The broad-spectrum regimen should also include metronidazole. Second-generation beta-lactamase-resistant cephalosporins (e.g. cefuroxime) are not effective against Gram-negative organisms, notably *Enterobacter*. The local regimen may take account of the dominant neonatal intensive care unit flora.
- Volume replacement: fluid losses from the circulation into the gut or abdomen are easily underestimated. Immediate management of suspected NEC includes appropriate volume replacement and circulatory support. Monitoring must include peripheral perfusion, peripheral–core temperature gradient, urine output and plasma bicarbonate or base excess.
- Regular blood gas analysis and early recourse to assisted ventilation if there is evidence of shock, increasing metabolic acidosis, respiratory distress, respiratory failure or apnoeic episodes.
- Maintenance of normal urea, electrolytes, calcium and hydration by daily or twice-daily adjustments to rate and composition of intravenous fluids; prompt treatment of intercurrent problems such as hypoglycaemia, jaundice and DIC.
- Transfuse to maintain haemoglobin: the platelet count may fall and platelet transfusion will be necessary if the count is below $30 \times 10^9/l$ or below $70 \times 10^9/l$ before surgery.

Table 29.20 Modified Bell's staging for necrotising enterocolitis (Bell et al. 1978; Walsh and Kliegman 1986)

STAGE	CLINICAL FINDINGS	RADIOGRAPHIC FINDINGS	GASTROINTESTINAL FINDINGS
I: Suspected	Apnoea and bradycardia, temperature instability, lethargy	Normal or mild ileus	Mild abdominal distension, increased gastric residuals
IIA: Confirmed Features of stage I plus:	Apnoea and bradycardia, temperature instability, lethargy	Ileus pattern with one or more dilated loops, bowel wall oedema, focal pneumatosis	Bloody stools, prominent abdominal distension, absent bowel sounds, mild abdominal tenderness
IIB: Confirmed severe Features of stage IIA plus:	Thrombocytopenia and mild metabolic acidosis	Any of: widespread pneumatosis, ascites or portal venous gas	Abdominal wall oedema, palpable loops, tenderness, sometimes cellulitis
IIIA: Advanced Features of stage IIB plus:	Mixed acidosis, oliguria, hypotension, coagulopathy, disseminated intravascular coagulation	Prominent loops, worsening ascites, no free air	Signs of peritonitis: marked tenderness and distension. Abdominal wall oedema and induration
IIIB: Advanced plus perforation Features of stage IIIA plus:	Shock, deterioration in laboratory values and vital signs	Pneumoperitoneum	Perforated bowel

- Consider removal of umbilical cannulae – balance the risks: if an umbilical artery catheter is the only arterial access in an ill baby of less than 1000 g birthweight the balance may be in favour of keeping the catheter in situ.
- Insertion of a percutaneous central venous line for total parenteral nutrition (TPN) if possible.
- TPN (Ch. 17) is always necessary in NEC, for which enteral starvation for at least 7–10 days is needed. During the first 24–48 hours, if very ill, amino acid load is reduced and lipid infusion is avoided. If NEC is not confirmed, feeds may be recommenced after 48–72 h, and TPN may not be necessary.
- Analgesics should be used liberally: infants with NEC suffer pain and considerable stress. An opiate infusion (e.g. morphine or diamorphine) is recommended. Opiate-induced apnoea is not a problem in a neonatal unit where intermittent positive-pressure ventilation is available.
- Barrier nursing: scrupulous hand washing will prevent most cross-infection; true barrier nursing may be needed in an outbreak of NEC.

The majority of babies with NEC who are managed medically recover steadily. Stage I suspected or unconfirmed disease (Table 29.20) should be managed with 3 days of bowel rest, and if the baby rapidly improves he or she is unlikely to have NEC. For all confirmed cases, antibiotics, enteral starvation and TPN are usually prescribed for at least 7 days from the time of recovery from the initial severe illness. Perforation most often occurs in the first 48 hours but may become apparent at any time. By 7–14 days from diagnosis, most infants are free of signs of infection and have a soft abdomen, normal bowel sounds and a normal abdominal X-ray. Enteral feeding can then be restarted using 0.5–1.0 ml/h for the first 24 hours and thereafter increased cautiously. Expressed breast milk is the feed of choice; alternatively a preterm formula or donor expressed breast milk is used. Most infants who recover without surgery will tolerate one of these milks (see below for alternative feeds).

Surgical

In all, 20–50% of infants with NEC require surgery (Beeby and Jeffrey 1992; Spitz and Stringer 1993; Lucas and Morley 1998; Rees et al. 2010).

Indications

The cardinal indications for surgery in NEC are:

- failure to respond to medical management
- formation of a mass
- perforation.

The commonest indication for surgery is clinical deterioration with intestinal perforation, confirmed in 40–70% of infants who required surgery (Rowe et al. 1994; Horwitz et al. 1995; Rees et al. 2005). The commonest site of perforation is the terminal ileum, and multiple perforations are not unusual (Rowe et al. 1994; Horwitz et al. 1995). Perforation may occur without visible gas on the plain abdominal radiograph. Paracentesis showing at least 0.5 ml of brown-stained fluid, or bacteria on Gram stain, usually indicates perforation. Paracentesis is not widely used in the UK (Spitz and Stringer 1993).

Clinical deterioration despite medical treatment is more difficult to define. Abdominal signs, including a fixed dilated loop of intestine on serial radiographs, abdominal wall erythema or the development of an inflammatory mass, point to the need for surgery, as does general worsening in the infant's condition or a failure of intra-abdominal signs to resolve (Spitz and Stringer 1993).

Operation

At surgery, bowel necrosis is most commonly ileocaecal, and in around a third is limited to the colon, but it may occur at any point in the gut. Extensive gut necrosis may be inoperable and lethal (Rowe et al. 1994). The choice of operation depends upon the extent of gut necrosis, the extent of NEC in non-necrotic gut and the general condition of the infant. Among the numerous surgical procedures described, some main options exist (Rescorla 1995; Rees et al. 2005).

The commonest procedure is laparotomy, resection of necrotic bowel and creation of a proximal stoma and a distal mucous fistula (Horwitz et al. 1995; Rescorla 1995; Rees et al. 2005; Pierro et al. 2010). This necessitates a second procedure to restore gut continuity. Large fluid, electrolyte and nutrient losses may occur through a small bowel stoma, especially when milk is reintroduced. This has led to earlier timing of the second procedure, which is often performed within 2 months of the initial surgery. Postoperative complications include systemic, wound and intra-abdominal sepsis, which, perhaps surprisingly, are unusual (Horwitz et al. 1995). Stoma-related complications, such as dehiscence, are unusual and less likely with good nutritional status. Suspected stricture in the distal limb necessitates contrast study and may be resected (Schimpl et al. 1994).

Secondly, in the infant who is stable, with well-circumscribed disease, gut resection and primary anastomosis may be performed as one procedure. This is favoured in infants weighing over 1000 g (Rees et al. 2005). Problems with losses from the stoma are avoided and hospital stay may be reduced (Spitz and Stringer 1993). Primary anastomosis may reduce the likelihood of stricture.

'Clip and drop', referring to resection of necrotic bowel, while viable bowel is clipped and returned to the abdomen, pending further laparotomy in the following days, is used in some centres (Rees et al. 2005).

An alternative strategy is peritoneal drainage, at times performed on the neonatal intensive care unit under local anaesthesia (Pierro et al. 2010). One or two soft drains are inserted into the right lower quadrant, with broad-spectrum antibiotic cover and nasogastric aspiration. Initially used in babies who were too ill for surgery, some may avoid surgery altogether. In our practice, peritoneal drainage alone is usually reserved for small infants who are clinically unstable and unsuitable for laparotomy. After peritoneal drainage, laparotomy remains necessary in many (Pierro et al. 2010).

Finally, in the group with a poor prognosis (Spitz and Stringer 1993), disease may be so extensive that resection cannot be performed. Such extensive disease is usually lethal. A proximal jejunostomy can be used to defunction distal bowel. A 'second-look' laparotomy is performed if the baby survives, to reassess possible resection.

Postoperative management

Nutritional support and intensive care are usually needed for 2–3 weeks. Enteral feeds are reintroduced slowly using breast milk if available, as described above. If milk is not tolerated, a lactose-free formula containing hydrolysed protein and medium-chain triglycerides is used and, in some centres, this is the feed of choice after NEC. If rapid gut transit and diarrhoea persist, loperamide may be used. In the infant who is tolerating feeds but not gaining weight, salt and water depletion, malabsorption and intestinal, systemic or urinary tract infection should be considered. Calories and protein may be added to breast milk using a commercial breast milk fortifier. Formula may be supplemented with a powdered carbohydrate/fat mixture in 2–5% solution, but this may provoke or exacerbate diarrhoea. Advice from a paediatric dietician is essential.

Fig. 29.30 Sites of intestinal stricture after necrotising enterocolitis. (Redrawn from Janik *et al.* (1981).)

Late strictures due to submucosal thickening and fibrosis (Schimpl *et al.* 1994) may have become more common. In the baby who does not need surgery, strictures are less common and shorter (Lamireau *et al.* 1996). Most strictures manifest within 6 weeks and almost all do so within 4 months (Schimpl *et al.* 1994). Overall strictures occur in 10–40% and, although some narrowing seen on contrast studies may resolve spontaneously, most strictures need surgery. Most are colonic but strictures occur at the site of anastomosis and in the small bowel (Janik *et al.* 1981) (Fig. 29.30). Short bowel syndrome (SBS) may require long-term management, especially if the ileocaecal valve has been resected (see below).

Outcome

In 5–10%, NEC relapse occurs, usually within a month of initial presentation. Management is the same. It is not clear if management of the first attack can alter risk of recurrence. Late complications are important (Table 29.21).

Overall survival after NEC is 70–90% (Rowe *et al.* 1994; Horwitz *et al.* 1995). Mortality is higher in infants of less than 28 weeks' gestation despite similar severity of disease. In babies with a birth-weight of less than 1000 g the survival rate is poor compared with larger infants (around 60% versus over 90%) (Chardot *et al.* 2003). Extensive disease, bacteraemia, DIC and persistent ascites are bad prognostic indicators (Kliegman and Fanaroff 1981; Rowe *et al.* 1994; Horwitz *et al.* 1995).

The nutrition, growth and gastrointestinal function of survivors depend upon the site and extent of disease and resection. In the absence of SBS (see below), major nutritional problems are unusual, although short-term problems with rapid gut transit, diarrhoea and malabsorption are seen as gut adaptation occurs (Liefgaard *et al.*

Table 29.21 Late complications of necrotising enterocolitis

- Recurrence
- Intestinal stricture
- Enterocyst
- Short gut syndrome
- Enterocolic fistula
- Anastomotic leak
- Cholestasis
- Malabsorption
- Atresias and aganglionosis
- Salt and water depletion
- Polyposis
- Treatment complications

1995). Specific nutritional deficiencies due to terminal ileal resection (particularly vitamin B₁₂) should not be forgotten.

Long-term neurodevelopmental follow-up is essential in view of the high rate of disability in survivors of severe NEC (Rees *et al.* 2007). Neurodevelopmental problems are more common after NEC (odds ratio 1.7 (1.3–2.2)) and in those needing surgery compared with those treated medically (odds ratio 2.3 (1.5–3.6)) (Rees *et al.* 2007). The link between NEC and periventricular leukomalacia may relate to common antenatal risk factors, or be the result of proinflammatory cytokine release or systemic illness and hypotension.

Prevention

Prevention in current practice includes:

- use of breast milk
- minimal enteral feeding (0.5 ml/h) for 7 days before increasing feeds
- slow feed advancement
- standardised feeding regimen
- probiotics.

Future progress in NEC lies in its prevention. Despite many suggested preventive strategies (Claud 2009), the central difficulty of studying a relatively infrequent, sporadic disease thwarts attempts at good, prospective, randomised studies.

In the term infant, avoidance of perinatal asphyxia might reduce NEC (Beeby and Jeffrey 1992; Clark and Miller 1996). In the infant with hypoxic–ischaemic encephalopathy, we avoid milk feeds during the acute encephalopathy and during cooling, starting low-volume feeds for at least 24 hours before full enteral feeding.

Maternal antenatal steroids reduce the risk of NEC by amelioration of preterm lung disease, or by a direct effect upon gut maturation and mucosal integrity (Claud 2009). Choice of antibiotic in preterm rupture of membranes is important, and co-amoxiclav should be avoided (Kenyon *et al.* 2001). The risk of NEC rises when antibiotics are continued for more than 5 days when cultures are negative (Cotton 2010). General measures including maintenance of good tissue perfusion, blood pressure and hydration and avoidance of hypotension, unnecessary H₂ receptor blockers, hypoxia and hypothermia are all likely to reduce NEC. In the preterm infant with hypotension resistant to volume expansion, inotropes improve gut perfusion (Hentschel *et al.* 1995). Umbilical artery catheters should be removed if there is evidence of thrombosis or reduced blood flow to buttocks or lower limbs. The role of blood transfusion is contentious. There is a temporal association with NEC after 4 weeks

of age (Josephson et al. 2010) but the transfusion may be given in response to premonitory symptoms of NEC or relate to immaturity and generalised illness. In many centres, feeds are withheld a few hours around and during transfusion, although there is no strong evidence base for this practice (Agwu and Narchi 2005).

The timing, method and composition of enteral feeds in the face of immaturity of digestion, absorption, gut motility and barrier function have attracted most attention (Newell 2000). Breast milk should be given, and lactation supported whenever possible (Lucas and Cole 1990; Meinzen-Derr et al. 2009). Freezing breast milk for storage does not abolish benefit (Dvorak et al. 2003). Meta-analysis suggests that donor breast milk will reduce the risk of NEC fourfold compared with formula (McGuire and Anthony 2003). A substantial reduction in NEC may be achieved with the use of a structured feeding regimen (Patole and de Klerk 2005). Hyperosmolar feeds should be avoided, and care should be taken when adding electrolytes to milk.

Prolonged delay in enteral feeding for the prevention of NEC cannot be recommended but rapid, incautious introduction and increase of enteral feeds in the face of poor feed tolerance is likely to lead to NEC (McKeown et al. 1992; Berseth 1994). In the VLBW infant, most advise introduction of milk feeds at 20–25 ml/kg/day, increased by the same amount daily (Berseth et al. 2003). Administration of small amounts of milk (minimal enteral feeding) is widely used to promote gut development (McClure and Newell 2000; Bombell and McGuire 2009) and does not increase NEC risk and may reduce it (Berseth et al. 2003). Special care is needed with the introduction of milk in the infant with intrauterine growth restriction (Ewer et al. 1993; Dorling et al. 2005). In intrauterine growth restriction with abnormal fetal Doppler studies, early introduction of milk on day 2 is safe, and has the advantage of earlier feed tolerance (Leaf et al. 2010).

Control of infection is essential in the management of epidemic NEC and is good practice in all cases. Prophylactic use of systemic antibiotics is not advised. Administration of enteral aminoglycosides is not without risk, as absorption may occur, but may reduce the risk of NEC (Fast and Rosegger 1994). Manipulation of intestinal flora during gut colonisation towards the pattern seen in the breastfed infant, by administration of probiotics (bacteria) or prebiotics (oligosaccharides which favour selection of these bacteria), looks promising for NEC prevention. Meta-analysis of trials of a wide variety of prebiotic regimens, varying in organism, dose and timing, demonstrates a risk ratio for NEC in those given these live bacterial preparations of 0.35 (0.23–0.55), with a number needed to treat of 25 (17–34) to prevent a case of NEC (Deshpande et al. 2010). This evidence may indicate the need for a change in practice (Tarnow-Mordi et al. 2010), although clear guidance cannot be drawn from current evidence, and further trials are in progress (Soll 2010). Changes in gut flora during initial colonisation may have lasting effects, even into adult life, raising potential unforeseen consequences (Mshvildadze and Neu 2010).

Future possibilities include modification of cytokine activity and treatment with growth factors (Claud 2009).

Short bowel syndrome

SBS follows loss of a significant portion of the small intestine and comprises malabsorption, diarrhoea and growth failure due to loss of mucosal surface area and rapid gastrointestinal transit. Loss of bowel may follow pre- or postnatal damage to the gut (Liefwaard et al. 1995; Stringer and Puntis 1995; Lao et al. 2010) (Table 29.22). NEC is the commonest cause of SBS and intestinal failure (Guarino and De Marco 2003), occurring at a time when, in fetal life, the

Table 29.22 Aetiology of short bowel

Prenatal
<ul style="list-style-type: none"> – Vascular accidents – Intestinal atresia – Abdominal wall defects – Volvulus – Meconium peritonitis
Postnatal
<ul style="list-style-type: none"> – Necrotising enterocolitis – Volvulus – Vascular thrombosis – Abdominal trauma

small intestine is doubling in length. Among infants with NEC who require surgery and survive, 4–10% have SBS (Köglmeier et al. 2008).

Babies with less than 50% of their total bowel length, or less than 100 cm of small bowel, are at high risk of SBS (Chaet et al. 1994; Liefwaard et al. 1995). Parenteral nutrition is usually needed when less than 40 cm of small intestine remains and is likely to be needed for longer if the ileocaecal valve is absent (Chaet et al. 1994).

The central tenet of management is nutritional support and maintenance of fluid and electrolyte balance, allowing gradual intestinal adaptation with bowel growth and mucosal hypertrophy (Chaet et al. 1994; Liefwaard et al. 1995; Stringer and Puntis 1995; Vanderhoof et al. 2003) and permitting full enteral feeds with as little as 10 cm of small bowel (Stringer and Puntis 1995). Most babies will achieve 90% absorption of carbohydrate and fats by 3 months (Liefwaard et al. 1995). Preservation of the ileum is important for adaptation, transit time and its unique ability to absorb vitamin B₁₂ and bile acids.

Babies with SBS cannot survive without TPN. When TPN is needed long-term, home administration has allowed these children a good quality of life (Puntis 2001). Enteral feeding is essential for adaptation but is often difficult. Most infants tolerate a protein hydrolysate, with medium-chain triglycerides and glucose polymers but no lactose, and some require an amino acid formula. Increased caloric content may be needed, and some require modular feeds, allowing manipulation of individual nutrient components. Specific nutrients may be used as primary therapy (Stringer and Puntis 1995). The diet must contain adequate calcium, magnesium, iron, fat- and water-soluble vitamins and trace elements. Vitamin B₁₂ supplements may be necessary after terminal ileal resection.

Possible pharmacotherapy includes oral decontamination regimens, antimotility drugs and hormonal therapies (Vanderhoof et al. 2003). Antimotility agents (loperamide) may be effective but should be used with care. The multidisciplinary team is key to successful management (Stringer and Puntis 1995; Puntis 2001). In intestinal failure, TPN dependence and associated complications, gut-lengthening surgery may be helpful. Procedures aim to slow intestinal transit time or increase absorptive surface area (Chaet et al. 1994; Stringer and Puntis 1995).

Small bowel transplantation is now available (Nayyar 2xnews2). Outcome after transplant has improved, with mean survival over 50% at 5 years. Two-thirds require liver transplant for SBS-associated liver disease, and survival varies with primary pathology, between 44% for NEC and 75% for volvulus (Lao et al. 2010).

The prognosis for SBS is now vastly better than it was 20 years ago, with survival rates exceeding 90%, even in those with less than

40 cm of small bowel. Most children climb back into the normal weight range by their third year, albeit on the lower centiles (Liefwaard et al. 1995).

Neonatal appendicitis

Appendicitis in the neonate is very rare, representing only 0.1–0.2% of childhood appendicitis (Jancelewicz et al. 2008). The commonest presentation is with perforation and diffuse peritonitis, with signs like those of NEC. Neonatal appendicitis may complicate NEC, Hirschsprung disease and cystic fibrosis and is more common in the preterm infant (Jancelewicz et al. 2008). Abnormal gas pattern on plain abdominal X-ray and red and white cells in the urine point to the diagnosis. Treatment is surgical, with intensive medical support and broad-spectrum antibiotic cover. Mortality is around 25%.

Intractable diarrhoea

Severe, protracted diarrhoea beginning soon after birth may be due to a congenital abnormality of gastrointestinal function. All are rare and investigation and management require the support of a specialist centre. Diarrhoea may be missed when watery stool is mistaken for urine in the nappy. Intestinal mucosal biopsy is indicated, and fluid and electrolyte balance and support of nutrition are the central objectives of treatment.

Microvillous inclusion disease (congenital microvillous atrophy)

This is an autosomal recessive disorder of the cytoskeleton of the apical region of the enterocyte in which there are atrophy and involution of microvilli of the small and large bowel (Canani et al. 2010). Massive diarrhoea is unresponsive to stopping feeds. To establish a diagnosis, mucosal biopsy is examined by electron microscopy. TPN is given but the poor prognosis has prompted use of small intestinal transplantation with good short-term survival (Bunn et al. 2000; Ruemmele et al. 2004).

Congenital electrolyte transport defects

Congenital chloride diarrhoea is autosomal recessive owing to a defect of the sodium-independent ($\text{Cl}^-/\text{HCO}_3^-$) exchanger in the ileum and colon due to recognised mutations near the cystic fibrosis gene (Canani et al. 2010). Fetal diarrhoea produces polyhydramnios. Severe watery diarrhoea, abdominal distension, hypochloaemic alkalosis and rapid weight loss occur in the newborn period. Stool chloride is high. Congenital sodium diarrhoea, due to defective sodium/proton exchange, produces a similar picture (Booth 1985). Intravenous, and subsequently oral, fluid and mineral replacement is necessary.

Congenital lactase deficiency

Symptoms immediately follow introduction of milk feeds, with acidic stools which contain lactose. Diagnosis is made by withdrawal of lactose-containing feeds and the demonstration of absent lactase activity on a jejunal mucosal biopsy. It is very rare compared with secondary lactose intolerance (Heyman 2006).

Congenital glucose/galactose malabsorption

Watery acidic stools containing reducing substances, but possibly not lactose, are seen in the first days after birth. After rehydration, a fructose-based formula is given and the prognosis is good (Canani et al. 2010).

Autoimmune enteropathy

Intractable diarrhoea, characteristically with a family history of autoimmune disease, may be due to immune dysregulation with a variety of genetic abnormalities (Canani et al. 2010). Immunosuppressive or immunomodulatory therapy offers benefit (Montalto et al. 2009).

Gastro-oesophageal reflux

Clinical presentation

Gastro-oesophageal reflux disease (GORD) is difficult to define, diagnose and treat (Birch and Newell 2009; Vandenplas and Rudolph 2009). GORD may lead to vomiting, oesophagitis, recurrent apnoea, pulmonary aspiration, exacerbation of bronchopulmonary dysplasia, poor growth and longer stay in hospital. Most episodes of reflux occur during transient relaxation of the lower oesophageal sphincter (Omari et al. 2002). Reflux is more common in infancy than in childhood. The preterm infant is at high risk because of low resting lower oesophageal sphincter pressure and slow gastric emptying (Newell et al. 1993). Reflux is often seen after repair of oesophageal atresia. Feeds, the supine position, nursing care and chest physiotherapy increase reflux (Newell et al. 1989; Ewer et al. 1999).

GORD is a common diagnosis, made in over 20% of preterm infants (Dhillon and Ewer 2004). The clinical syndrome is difficult to define, and often the diagnosis is inferred from a positive response to a trial of therapy. Some infant behaviour patterns are associated with reflux, lending support to a score based upon clinical observations (Feranchak et al. 1994). Respiratory deterioration or recurrent apnoea without apparent precipitating cause, and resistant to usual therapy (e.g. caffeine), may respond to reflux therapy.

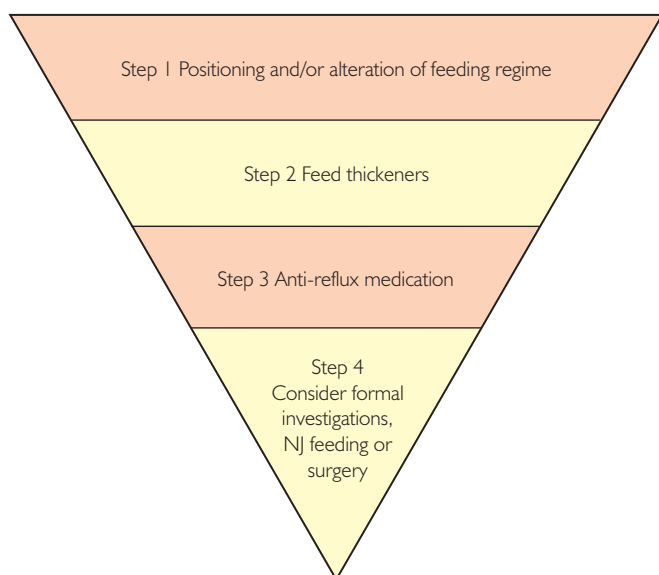

Investigations have poor predictive value. Contrast studies lack sensitivity but rule out anatomical abnormality (Dhillon and Ewer 2004). Prolonged oesophageal pH study, the gold standard in children, is limited by milk buffering of gastric acidity (Omari and Davidson 2003). Reference pH data vary according to prematurity and intensive care (Table 29.23) (Vandenplas and Sacre Smits 1987; Newell et al. 1989; Vandenplas et al. 1991; Ng and Quak 1998). Impedance monitoring and scintigraphy detect reflux that is not evident on pH study, but are largely confined to research (Dhillon and Ewer 2004; Lopez-Alonso et al. 2006; Birch and Newell 2009). The presence of acidic oropharyngeal secretions on litmus testing has a high positive predictive value for acid reflux (James and Ewer 1999).

Treatment

Best practice is difficult to define in the face of a limited evidence base for therapy (Birch and Newell 2009; Vandenplas and Rudolph 2009). We propose an inverse-pyramid, stepwise approach (Fig. 29.31). Prone or left lateral positioning, with cardiorespiratory monitoring, can be used while the infant is in hospital (Ewer et al. 1999; Omari et al. 2004). Clearly the prone position cannot be used

Table 29.23 Upper limits of reference range (median) for results of pH studies in infants without symptoms of gastro-oesophageal reflux

	NICU PRETERM INFANTS (Newell et al. 1989) (n = 35)	HEALTHY PRETERM INFANTS (Ng and Quak 1998) (n = 21)	INFANTS (Vandenplas et al. 1991) (n = 509)	CHILDREN 14–16 MONTHS (Vandenplas and Sacre Smits 1987) (n = 15)
Reflux index (%)	11 (3)	3 (1.1)	10 (4)	6.4 (2.7)
Episodes/24 h	29 (9.5)	30 (7.6)	70 (27)	46 (19)
Episodes >5 min/24 h	7 (3)	3 (1.1)	9 (3)	4.6 (2.2)

NICU, neonatal intensive care unit. The first study refers to preterm infants in neonatal intensive care units, the others to healthy infants. Almost all were receiving feeds.				

**Fig. 29.31** The inverse pyramid of gastro-oesophageal reflux disease therapy. Most babies need only steps 1 or 2. NJ, nasogastric.

at home, with increased risk of sudden infant death syndrome. Feed thickening reduces regurgitation and is widely used. The prokinetic effects of erythromycin or domperidone suggest that they should reduce reflux, but evidence of efficacy is limited. Pain or irritability may suggest oesophagitis, and treatment with ranitidine or a proton pump inhibitor is often used. Surgical fundoplication is rarely necessary and is considered in recurrent aspiration, reflux-related life-threatening events or where severe reflux disease is unresponsive to medical therapy (Kiely 1990). In GORD resistant to therapy, transpyloric feeding may assist, and cow's milk protein intolerance (MPI) should be considered (Misra et al. 2007; Birch and Newell 2009; Vandenplas and Rudolph 2009).

Prognosis is good and in most infants reflux resolves with maturation of the antireflux barrier. Persistent reflux is more common in those with neurodevelopmental problems.

Table 29.24 Gastrointestinal manifestations of milk protein intolerance

- Vomiting
- Gastro-oesophageal reflux
- Diarrhoea
- Failure to thrive
- Colic
- Colitis
- Villous atrophy and malabsorption
- Eosinophilic gastroenteropathy
- Occult blood loss

Milk protein intolerance

Antigens provoking MPI include cow's milk whey proteins, β -lactoglobulin, α -lactalbumin and casein. Immunogenic proteins may be absorbed and secreted in breast milk, explaining cow's milk colitis in exclusively breastfed infants (Vandenplas et al. 2007). In the newborn, gut barrier function is poor (Table 29.15) and macromolecular absorption is high, although this does not fully account for allergic reactions. MPI may follow any gastrointestinal insult, such as NEC or surgery.

Over 90% of MPI presents in the first months of life, with an overall incidence of 2–5%, although over 50% with an atopic family history may develop MPI. Infants with MPI often react to other antigens.

Clinical features

The commonest gastrointestinal symptoms are vomiting and diarrhoea (Table 29.24) (Vandenplas et al. 2007). GORD is strongly linked with MPI. MPI is the commonest cause of colitis in the young infant, with rectal bleeding with loose stools containing mucus. MPI enteropathy may result in weight loss, abdominal distension and steatorrhoea with patchy subtotal villous atrophy and crypt hyperplasia. MPI may be accompanied by lactose intolerance. Non-gastrointestinal symptoms of MPI range from acute reactions, including urticaria, to chronic atopic disease. Anaphylaxis is rare in the neonate.

Diagnosis rests upon remission of symptoms on exclusion diet and relapse on challenge. Estimation of total IgE and specific antibodies (radioallergosorbent test) or skinprick testing may assist diagnosis and suggest prognosis (Vandenplas et al. 2007). A hypo-allergenic, lactose-free, milk substitute containing extensively hydrolysed proteins or an amino acid-based formula is given. Infants with severe MPI, notably colitis, are more likely to require an amino acid formula. If breastfed, restriction of maternal diet, avoiding cow's milk and sometimes egg and soya, is recommended (Vandenplas et al. 2007). Soya milk is not recommended in MPI, and is not given before 6 months of age (Agostoni et al. 2006). Goat's milk is only suitable for goats.

Management demands close dietetic supervision. Challenge, to substantiate diagnosis and demonstrate resolution of MPI, can usually be performed under medical observation but out of hospital (Vandenplas et al. 2007). The vast majority of MPI resolves in the first 3 years.

Prevention

Early breastfeeding prevents atopic symptoms. Preventive strategies include exclusive breastfeeding and avoidance of solid foods for at least 4 months. In atopic families, hydrolysed formula prevents eczema (Berg et al. 2010). Immunomodulation may be important, using probiotic (*Lactobacillus*) (Kalliomaki et al. 2003) or prebiotic (Moro et al. 2006).

Pancreatic disease

Cystic fibrosis

Cystic fibrosis is an autosomal recessive condition affecting 1:3000 live births (Massie et al. 2010). The cystic fibrosis transmembrane conductance regulator (CFTR) regulates chloride and electrolyte transport across the cell membrane (Doull 2001; Welsh 2010). The commonest mutation is a single amino-acid substitution, $\Delta F508$, which interferes with folding of CFTR so that it is held and degraded by the endoplasmic reticulum. Five classes of mutation are recognised and relate to prognosis and to potential therapy. In class I defects, where CFTR is not produced, for example, aminoglycosides inhibit the effect of a mutant stop codon so that full-length CFTR is made. Around 1000 mutations are known and result in a wide range of severity and clinical phenotype. The carrier rate of cystic fibrosis mutations is about 1:25.

Screening

Fetal diagnosis and family planning have reduced the incidence of cystic fibrosis by 17–30% (Massie et al. 2010). Neonatal screening uses the dried blood spot collected in the first week. Serum immune reactive trypsin is elevated in almost all infants with cystic fibrosis, but specificity is poor and so screening now includes DNA mutation analysis (Massie et al. 2010). Neonatal screening is now in place across Europe and North America. The detection of presymptomatic infants offers the chance to provide beneficial early management led by an expert multidisciplinary team from a cystic fibrosis centre, improving nutritional status and with anticipated long-term benefits (Borowitz et al. 2009; Robinson et al. 2009; Sermet-Gaudelus et al. 2010).

Clinical presentation

Most newborns with cystic fibrosis are asymptomatic and found on screening, but neonatal cystic fibrosis may present clinically (Table

Table 29.25 Neonatal presentations of cystic fibrosis

- Antenatal mutation analysis
- Fetal hyperechogenic bowel
- Fetal gut dilatation
- Fetal intra-abdominal calcification
- Neonatal screening
- Meconium ileus
- Cholestasis
- Meconium peritonitis
- Respiratory infection
- Exocrine pancreatic insufficiency
- Failure to thrive

29.25). Fetal echogenic gut, noted on ultrasound, may mark cystic fibrosis, but it has a low predictive value (Stringer et al. 1996). A total of 10–15% of cystic fibrosis presents with meconium ileus resulting in intestinal obstruction within 48 hours of birth. It is associated with pre- or postnatal perforation, volvulus, chemical or bacterial peritonitis, intestinal atresia and microcolon. Conservative management with intravenous fluids, antibiotics and water-soluble, hyperosmolar contrast enema under fluoroscopic control should only be attempted in a specialised centre in collaboration with a paediatric surgeon. Neonatal mortality in meconium ileus is 10–20% but in survivors outcome is similar to that seen in other children with cystic fibrosis (Coutts et al. 1997).

Cystic fibrosis should not be forgotten as a cause of neonatal cholestasis. Liver function tests are abnormal but liver biopsy may not be diagnostic. Ursodeoxycholic acid is used and jaundice usually clears in infancy.

Sweat testing is possible in the neonatal period but is best attempted from 6 weeks postterm. A single sweat test is not diagnostic. Mutation analysis is usually diagnostic but there remain some unknown mutations.

Management

The support needed by the family whose baby has cystic fibrosis is considerable (Borowitz et al. 2009). The most important management step is referral to a specialised multidisciplinary team (Borowitz et al. 2009; Robinson et al. 2009; Sermet-Gaudelus et al. 2010). Confirmation of diagnosis, genetic counselling, nutritional supervision and monitoring of respiratory function are needed by all. Breastfeeding should be encouraged. Breast milk has lipolytic and anti-infective properties. Alternatively, a standard infant formula is used. Sodium supplements (2 mmol/kg/day) may be necessary. Energy supplements are provided if growth is suboptimal (Table 29.26). A lactose-free hydrolysed protein feed containing medium-chain triglycerides may be better tolerated after meconium ileus. Over 90% of European children with cystic fibrosis have pancreatic insufficiency with fat malabsorption by 12 months of age (Borowitz et al. 2009; Sermet-Gaudelus et al. 2010). Faecal elastase provides a convenient measure of pancreatic function and is reliable even in the preterm from 2 weeks of age. Enzyme replacement therapy is needed by all who are pancreatic-insufficient. Fat-soluble vitamin supplements are given.

Respiratory infection is treated aggressively. Chest physiotherapy to encourage clearance of secretions is commenced in the first months. Evidence does not support the use of prophylactic long-term antibiotics. Influenza immunisation is given and passive immunisation against respiratory syncytial virus is considered. Tobacco smoke exposure must be avoided.

Table 29.26 Nutritional management of cystic fibrosis (Borowitz et al. 2009; Sermet-Gaudelus et al. 2010)

Energy	
Routine	100–130 kcal/kg/day
Poor growth	150–200 kcal/kg/day
Milk	
Routine	Breast milk Standard infant formula
Poor growth	High-energy infant formula or supplement formula with glucose polymer or fat emulsion and glucose polymer or mixed fat and carbohydrate
Postoperative period, after meconium ileus or milk protein intolerance	Hydrolysed protein milk with medium-chain triglycerides
Pancreatic enzymes (acid-resistant microspheres)	
2000 IU lipase/100 ml milk	
Mix with milk or water and give immediately from a spoon before a feed	
Vitamins (daily dose)	
Vitamin A	1500 IU
Vitamin D	400 IU
Vitamin E	40–50 IU
Vitamin K	300 µg

Schwachman–Diamond syndrome

Pancreatic exocrine insufficiency is rare other than in cystic fibrosis. Pancreatic hypoplasia, isolated enzyme deficiencies and a number of rare syndromes (e.g. Johanson–Blizzard, Pearson's) may be associated with malabsorption.

Schwachman syndrome comprises pancreatic exocrine insufficiency, usually presenting in infancy, and variable or cyclical neutropenia, which may lead to clinical immunodeficiency. Short stature and metaphyseal dysplasia are characteristic. Pancreatic enzyme replacement is needed in infancy.

Part 4: Congenital defects and surgical problems

Ian Sugarman Mark D Stringer Alistair G Smyth

Introduction

This chapter discusses the management of major surgical conditions affecting the neonatal alimentary tract. Most are congenital malformations and, as such, are frequently multiple. Conditions are discussed in sequence down the gut, rather than in order of importance or severity. Some preliminary general comments about neonatal gastrointestinal surgery are necessary.

The survival of babies with congenital malformations has improved progressively as a result of advances in neonatal care and the concentration of these infants within specialist paediatric surgical units. An integrated multidisciplinary approach is essential in the management of premature surgical neonates and in those with complex congenital malformations (British Association of Paediatric Surgeons/Royal College of Surgeons of England 1999).

Prenatal ultrasound diagnosis of major structural gastrointestinal anomalies presents parents and clinicians with the opportunity to terminate the pregnancy or to deliver the baby in a centre with ready access to paediatric surgical expertise; in rare instances, fetal intervention may be appropriate (Ch. 9). Prenatal diagnosis of gastrointestinal anomalies has had a major impact on the management of anterior abdominal wall defects in particular, not least because parents can be informed about management and prognosis. In other conditions, interpretation of ultrasound findings is less clear-cut. For example, hyperechogenic fetal bowel (bowel of similar or greater echogenicity than surrounding bone; Fig. 29.32) may indicate the presence of meconium ileus, cytomegalovirus infection or

intestinal obstruction but it is a relatively soft marker of fetal pathology and most affected fetuses are normal after birth (Stringer et al. 1996). Similarly, intestinal dilatation is non-specific and may be seen in the fetus with midgut or hindgut atresia, meconium ileus, malrotation or Hirschsprung disease (Richards and Holmes 1995).

Many congenital gastrointestinal malformations present with symptoms and signs of intestinal obstruction in the newborn.

Fig. 29.32 Sonographic cross-section of the fetal abdomen at 18 weeks' gestation showing hyperechogenic fetal bowel as bright as bone (arrows).

Vomiting

This will be bile-stained if the obstruction is beyond the level of the ampulla of Vater. Bilious vomiting in the newborn should be attributed to intestinal obstruction until proven otherwise. In one prospective study of 63 consecutive neonates with bilious vomiting, a surgical cause was identified in 24 (38%): Hirschsprung disease in nine, small bowel atresia in five, intestinal malrotation in four, meconium ileus in three, meconium plug in one, colonic atresia in one and milk inspissation in one (Godbole and Stringer 2002). Most of these babies had abdominal signs and an abnormal abdominal radiograph. No surgical cause for bilious vomiting was found in 39 (62%) infants, whose symptoms resolved with conservative management. All neonates with bilious vomiting require careful review with a very low threshold for further investigation. Intestinal malrotation must be excluded. First-line investigations consist of a detailed clinical examination, a plain radiograph of the chest and abdomen, routine haematology and biochemistry, and blood and urine cultures. A more detailed septic screen may be indicated. Abdominal ultrasound and gastrointestinal contrast studies are often warranted and, in selected cases, a rectal biopsy may be necessary.

Abdominal distension

An algorithm for assessing a baby who develops marked abdominal distension soon after birth is shown in Figure 29.33. This must be interpreted in conjunction with the baby's gestational age and general condition.

Delay or failure to pass meconium

Over 95% of healthy term infants pass their first stool within 24 hours of birth (Sherry and Kramer 1955). Delayed passage of meconium after 48 hours in a term infant should always suggest the possibility of intestinal obstruction. However, such a delay is normal in premature infants (Weaver and Lucas 1993). In any baby who fails to pass meconium normally, the anus should be examined and its patency confirmed.

All babies with clinical features of intestinal obstruction should receive parenteral vitamin K. Bleeding is a rare manifestation of congenital gastrointestinal anomalies and more often indicates acquired disease. Upper gastrointestinal bleeding may be due to swallowed maternal blood, vitamin K deficiency bleeding or oesophagitis/gastritis. Peptic ulceration occurs occasionally and can be confirmed by endoscopy. Rectal bleeding in an otherwise well baby is most commonly due to an anal fissure or cow's milk protein intolerance. In a sick infant it may be from necrotising enterocolitis or malrotation with volvulus.

Mouth and nasopharynx

Cleft lip and palate

Cleft lip and palate is the commonest congenital anomaly in the craniofacial region, with an incidence in the UK of approximately 1:700 live births. Most clefts are diagnosed at birth but the diagnosis may be made by prenatal ultrasound scan. Cleft lip is twice as

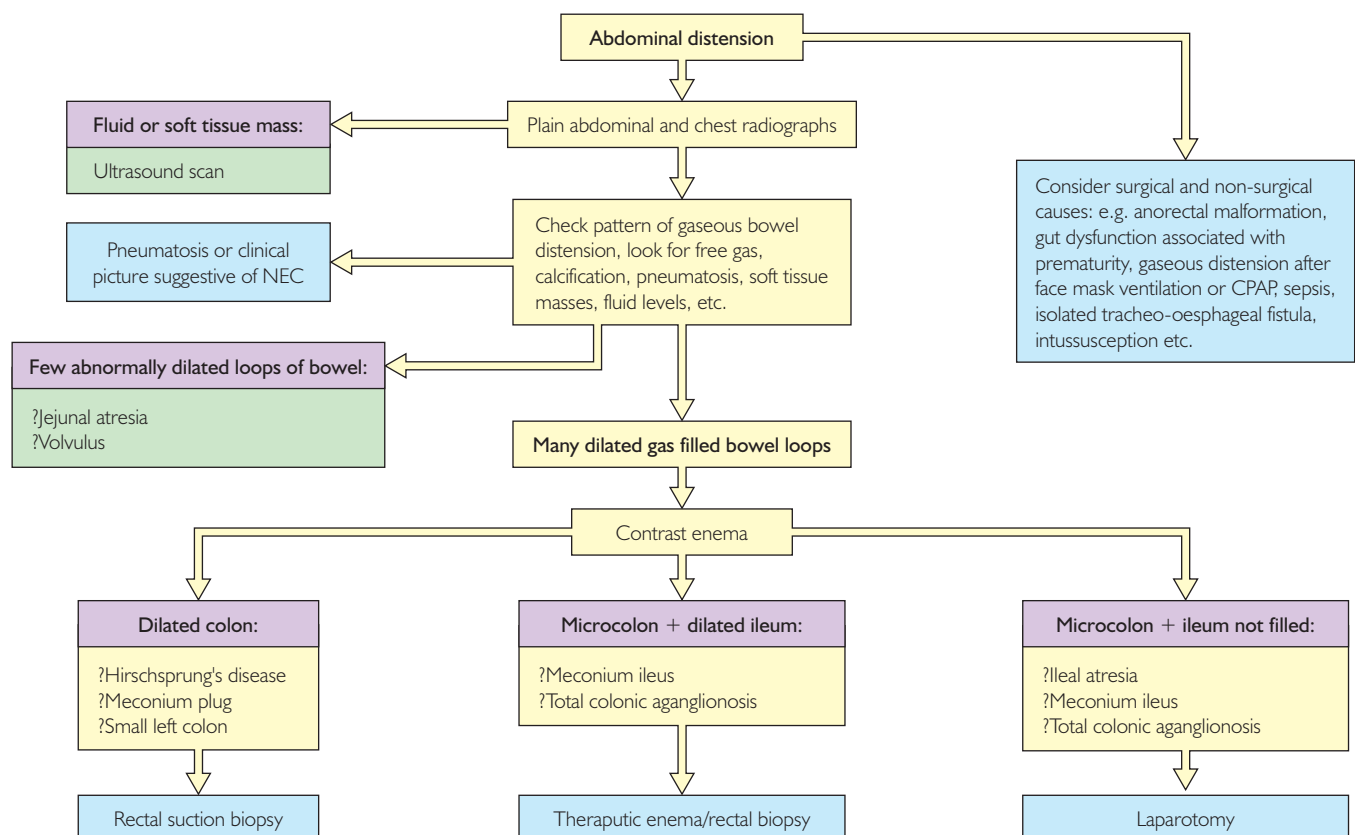

Fig. 29.33 An algorithm for investigating the neonate who develops abdominal distension soon after birth. This must be interpreted in conjunction with clinical and routine laboratory assessments. CPAP, continuous positive airway pressure; NEC, necrotising enterocolitis.

Fig. 29.34 Unilateral incomplete cleft lip.

Fig. 29.35 Complete cleft lip and lower lip pits (Van der Woude syndrome).

common on the left side than on the right but the reason for this remains obscure. Cleft lip with or without cleft palate is more than twice as common in males, whereas cleft palate alone is twice as common in females. In most patients the orofacial cleft will be the only defect. However, approximately 15% of all patients with cleft lip and/or palate will have other associated abnormalities, which together may form part of a recognised syndrome. With regard to non-syndromic cleft lip and palate, a family history of the condition may be present or a history of maternal exposure to drugs such as phenytoin. All babies presenting with cleft lip and/or palate should have a full examination and a standard karyotype investigation.

Isolated cleft palate accounts for about 50% of all clefts, the remaining groups consisting of unilateral cleft lip and palate (20%), cleft lip (20%) and bilateral cleft lip and palate (10%). This complex deformity can affect many aspects of development, including speech, hearing, facial appearance, dental development and facial growth. Treatment requires a multidisciplinary approach from birth to maturity. Outcomes can be remarkably good when this is provided in a skilled and coordinated manner and remarkably bad when it is not (Shaw et al. 1996).

Cleft lip and palate services within the UK changed dramatically following the 1998 Clinical Standards Advisory Group report into cleft lip and palate services and treatment outcomes. This document recommended a reduction in cleft units within the UK from the previous 57 units to 8–15 specialist centres, allowing a concentration of expertise and resources. All patients should be cared for within a dedicated multidisciplinary cleft team with full access to the necessary specialist services.

Cleft lip

A cleft lip may result when fusion between the medial and lateral nasal processes with the maxillary process fails to occur. Cleft lip may occur in isolation or in conjunction with cleft palate. The lip cleft is usually to one side of the midline and may be incomplete (Fig. 29.34) or involve the full height of the lip (complete), extending into the floor of the nose. The cleft may be unilateral or bilateral and may extend on to the gum area (alveolus) of the upper jaw. Babies with isolated cleft lip usually manage to feed well from a soft bottle with teat and in many cases may also successfully breastfeed.

A rare midline cleft of the upper lip may occur as part of an orofacial-digital syndrome (type I). Cleft lip can also occur in conjunction with lower lip pits – Van der Woude syndrome (Fig. 29.35), an autosomal dominant condition with variable expressivity.

Outcomes from cleft lip treatment are often excellent and surgical repair is usually undertaken at around 3 months of age using a

Fig. 29.36 Cleft lip and nose repair (same child as in Fig. 29.34).

modification of the Millard rotation-advancement method of repair. This includes a careful realignment and repair of the mid-facial and labial muscles. Primary nasal correction is carried out at the same time as lip repair (Fig. 29.36). In complete cleft lip and palate, the anterior palate (hard palate) is often repaired with a vomerine flap at the same time as the cleft lip repair. The alveolar bony cleft is usually not repaired at the same time as primary lip or palate surgery owing to maxillary growth impairment in the growing child, but delayed into later childhood.

Cleft palate

Palatal fusion begins around the 8th week of intrauterine life and occurs from the front of the palate to the back. Interference with palatal shelf fusion from extrinsic factors such as phenytoin or intrinsic factors such as genetic predisposition or obstructing tongue position may result in a cleft palate. Cleft palate may occur in isolation or in combination with cleft lip. Isolated cleft palate may involve the posterior palate alone (soft palate) or may extend further forward into the hard palate up to the incisive foramen just behind the front teeth (complete cleft palate). Cleft palate is a midline defect and may be incomplete or complete (Fig. 29.37).

Isolated cleft palate cannot be diagnosed antenatally and is noted after birth. Nasal regurgitation of milk is not pathognomonic of cleft palate and exclusion requires direct inspection of the full palate with a good light source with the tongue depressed. Digital palpation of the palate by itself is not sufficient, as incomplete clefts can

Fig. 29.37 Isolated cleft palate (seen at time of surgery).

Fig. 29.38 Pierre Robin sequence (note micrognathia).

Fig. 29.39 Wide U-shaped cleft palate (Pierre Robin sequence).

Fig. 29.40 Submucous cleft palate showing bifid uvula and midline groove/translucent line of soft palate.

be easily missed (Ch. 14). Babies with cleft palate have difficulty with suction and are unlikely to breastfeed properly. Assisted feeding (of formula or expressed breast milk) is often required using a soft bottle and teat. Midline clefts such as cleft palate are more likely to be associated with a chromosomal defect and therefore all babies born with cleft palate should have a fluorescent in situ hybridisation test for a chromosomal microdeletion on chromosome 22 (Catch-22, see Ch. 31) as well as a standard karyotype.

Pierre Robin sequence (Fig. 29.38) is the association of an often wide U-shaped cleft palate (Fig. 29.39) with a small mandible (micrognathia) and a posteriorly placed tongue. Upper airway obstruction is a common association, which may require intervention such as positioning the infant (side or prone) or insertion of a nasopharyngeal airway. Tracheostomy is rarely required. Pierre Robin-associated syndromes should be considered, such as Stickler syndrome and velo-cardio-facial syndrome (22q11 deletion).

Surgical repair of cleft palate is usually carried out at around 8–9 months of age using local tissues and includes repair of the soft palate muscles. When possible, cleft palate should be repaired before 18 months of age as later repairs are associated with reducing outcomes in speech quality. In Pierre Robin sequence cleft palate, the repair may be delayed to 1 year of age or older, depending on the degree of micrognathia and associated airway obstruction.

A subtype of cleft palate called a submucous cleft palate is often difficult to diagnose and typically may not present until the child

is 4 or more years of age, often with accompanying speech problems. Indicators of a submucous cleft palate may include a bifid uvula, midline translucent zone of the soft palate and a palpable notch at the back of the hard palate (Fig. 29.40).

Children with a history of cleft palate require screening for chronic otitis media with effusion, which may require insertion of grommets or provision of a hearing aid. Speech and language monitoring is required for the possible development of cleft-type characteristics and velopharyngeal incompetence during speech.

Alveolar bone grafts

Clefts that involve the gum area (alveolus) of the upper jaw may benefit from the insertion of a bone graft to allow tooth eruption, provide bone support for the teeth and upper jaw and close off any remaining fistula. Secondary bone grafting just before the eruption of the permanent canine tooth produces the best outcome and is usually carried out between 9 and 11 years of age (Fig. 29.41).

Other facial clefts

Other, more extensive facial clefts are rare. The pathogenesis of these facial clefts such as the lateral and oblique facial cleft remains uncertain. The soft-tissue clefts frequently involve the underlying facial bones and the orbit and a careful search is required for associated anomalies, including the central nervous system.

Fig. 29.41 Radiographs before (A) and 6 months after (B) alveolar bone graft operation.

Multidisciplinary management

Cleft lip and palate is a complex abnormality that demands coordinated care and treatment from a number of specialists and in the last 20 years there has been an increasing emphasis on the importance of the multidisciplinary team (Watson et al. 2001). The core team often consists of a cleft surgeon, orthodontist, speech and language therapist, paediatrician, clinical psychologist, clinical geneticist and specialist cleft nurses. While treatment interventions should be restricted to specific times to facilitate good outcomes and minimise the burden of care, follow-up by the cleft team is often required until growth has stopped (18–20 years of age). The Cleft Lip and Palate Association is an active parent/patient support group within the UK providing essential feeding equipment and information.

The provision of high-quality primary surgery reduces the need for future interventions and evidence is accumulating in support of high-volume operators achieving better outcomes (Williams et al. 1999). However, despite expert initial care, including surgery, some patients may require further operative procedures to improve speech (pharyngoplasty) or in early adult life to benefit facial appearance and function (rhinoplasty and orthognathic surgery).

Oesophagus and stomach

Oesophageal atresia

The commonest type of oesophageal atresia, accounting for 85% of all cases, consists of a dilated, blind-ended upper oesophageal pouch and a narrow, distal tracheo-oesophageal fistula (TOF; Fig. 29.42A). Nearly 10% of infants with oesophageal atresia do not have a fistula but have a long gap between the oesophageal segments (Fig. 29.42B). Rarely, there is a fistula between the upper oesophageal pouch and the trachea, with or without a distal fistula (Fig. 29.42D, E). An isolated TOF ('H' or 'N' fistula) is usually grouped with these anomalies, although there is no atresia (Fig. 29.42C). More detailed classifications of oesophageal atresia have been reported (Kluth 1976). The incidence of this spectrum of disorders is about 1:3500 births.

The trachea and oesophagus both develop from the primitive foregut but the pathogenesis of oesophageal atresia/TOF is uncertain. Some experimental studies have suggested that this malformation results from an abnormal separation of the primitive trachea and oesophagus while others have indicated that the fistula develops after these structures have separated. Oesophageal atresia is usually sporadic and rarely familial.

Maternal polyhydramnios and a small or absent fetal stomach bubble may suggest the possibility of oesophageal atresia prenatally

but these sonographic findings are not specific (Stringer et al. 1995a). Occasionally, a dilated upper oesophageal pouch may provide further evidence. Additional malformations suggestive of trisomy 13 or 18 or the VACTERL association (vertebral defects, anal atresia, TOF, radial and renal dysplasia with cardiac and limb defects) may be detected by prenatal ultrasound.

Postnatally, the baby typically dribbles frothy saliva and has episodes of choking, coughing and cyanosis, often precipitated by attempts to feed. This is caused by overflow of secretions into the larynx and trachea. Attempted passage of a 10–12 Fr radiopaque nasogastric tube will reveal a hold-up about 10 cm from the lips (a smaller tube tends to curl up in the upper pouch). The diagnosis is confirmed by anteroposterior and lateral radiographs of the chest with the tube in situ (Figs 29.43 and 29.44). Air in the stomach indicates a TOF while a gasless abdomen usually signifies atresia without a fistula.

Associated congenital anomalies occur in 50% or more of infants (Chittmittrapap et al. 1989). Cardiovascular, genitourinary, skeletal and anorectal anomalies are found frequently. An echocardiogram, urinary tract ultrasound scan and radiographs of the chest, abdomen and spine will detect many of these additional malformations at an early stage. The VACTERL cluster has already been described. Duodenal atresia is the commonest associated gastrointestinal anomaly. Rarely, oesophageal atresia may be associated with the CHARGE association (coloboma, heart defects, choanal atresia (Ch. 31), retarded development and growth, genital hypoplasia and ear anomalies) (Kutiyawala et al. 1992) or with midline defects such as cleft lip and palate and exomphalos.

Initial management is aimed at keeping the airway free of secretions and excluding additional major malformations. It is rarely necessary to operate immediately. The infant should be placed slightly head-up, with a 10 Fr double-lumen Replogle tube in the proximal pouch on continuous low-pressure suction. Routine neonatal care will include regulation of temperature, fluid balance and blood glucose. As soon as the baby is stable, he or she should be transferred to a neonatal surgical unit.

The vast majority of neonates with oesophageal atresia/TOF can be treated successfully by surgical division of the fistula between the trachea and oesophagus and primary anastomosis of the oesophagus. This was first successfully accomplished in 1941 (Haight and Towsley 1943). The operation is usually performed through a small right thoracotomy but minimally invasive repair using a thoracoscope is becoming more commonplace (Rothenberg 2002). A preliminary tracheoscopy is often carried out to search for an upper pouch fistula and to clarify the anatomy (Fig. 29.45). Postoperatively, after a straightforward operation, feeding is commenced enterally via a transanastomotic nasogastric tube or by mouth.

Fig. 29.42 Schematic representation of the spectrum of oesophageal atresia/tracheo-oesophageal fistula.

Two specific problems should be mentioned.

1. The baby with oesophageal atresia/TOF and severe respiratory distress (associated with prematurity or secondary to acid aspiration via the fistula) is in danger. The fistula provides a low-resistance pathway for inspiratory gases, thus preventing efficient ventilation. Gastric distension (and subsequently rupture) further compromises ventilation (Figs 29.46 and 29.47). Various temporising measures may be helpful, such as positioning the tip of the endotracheal tube below the fistula, using low-pressure ventilation or attempting balloon catheter occlusion of the fistula, but the definitive treatment is emergency ligation of the fistula (Spitz 1996). Gastrostomy is hazardous because it provides an even easier pathway for the escape of respiratory gases.
2. The baby with long-gap oesophageal atresia may have oesophageal atresia without a fistula or a distal TOF but a wide gap between the oesophageal segments. In the former, surgery is typically delayed (delayed primary anastomosis). The upper and lower pouches are allowed to elongate and hypertrophy over a period of up to 3 months and can eventually be anastomosed. During this time the baby is fed

Fig. 29.43 Oesophageal atresia. Note the coiled feeding tube in the proximal pouch. Also note the vertebral and rib abnormalities. Distal gas confirms a tracheo-oesophageal fistula.

through a gastrostomy and the upper pouch is kept clear of secretions. This can be expedited by the Foker technique, which involves placing sutures on the upper and lower pouch and pulling them together by constant traction; this avoids the need for a gastrostomy (Foker et al. 2005). In wide-gap oesophageal atresia/TOF, the anastomosis is sometimes possible under tension. After the repair, disruptive forces at the anastomosis are minimised by electively paralysing and ventilating the baby for 5 days with the neck flexed. Alternatively, the proximal oesophagus can be lengthened by dividing its outer muscle (myotomy) or by tubularising a proximal flap. In some cases, the oesophagus has to be abandoned – the TOF is divided and a cervical oesophagostomy and gastrostomy are fashioned (Fig. 29.48). The baby is sham-fed and scheduled for oesophageal replacement (using the stomach or a segment of colon) when thriving.

Most infants can expect a good outcome after repair of oesophageal atresia/TOF but numerous complications may occur. An anastomotic leak is uncommon and typically manifests as a pneumothorax or sepsis; conservative management with chest drainage, antibiotics and nutritional support is usually sufficient. In contrast, an anastomotic stricture is common but is easily treated by oesophageal dilatation. Gastro-oesophageal reflux is also common and requires antireflux medication. Intractable symptoms or reflux associated with a recalcitrant anastomotic stricture may merit fundoplication. A recurrent TOF is rare and presents with

recurrent pneumonia, sometimes in the older child. In oesophageal atresia, the trachea is floppy and tends to collapse anteroposteriorly on expiration (tracheomalacia). Consequently, most children have a typical barking cough ('TOF cough'). In most, the tracheomalacia tends to improve during infancy but, in some cases, life-threatening cyanotic episodes develop, requiring treatment by aortopexy and/or tracheopexy. All these complications can present with feeding difficulties and/or respiratory symptoms. Despite these problems, most children and adults enjoy a good quality of life after repair of oesophageal atresia/TOF (Chetcuti et al. 1988). In the UK, the Tracheo-Oesophageal Fistula Support (TOFS) group provides information for parents of affected children and a forum for sharing problems (www.tofs.org.uk) (Martin 1999).

The two most important factors determining survival are very low birthweight and major congenital cardiac defects (those causing cardiac failure or requiring surgery). Without either factor, predicted survival is greater than 95%. With one factor present it is 60% and with both it is only 20% (Spitz 1996).

Tracheo-oesophageal 'H' fistula

Congenital tracheo-oesophageal fistula without oesophageal atresia accounts for about 4% of all infants within the oesophageal atresia spectrum. It typically presents in the neonatal period with choking or cyanotic episodes associated with feeding. Some infants have marked gaseous abdominal distension from swallowed air. Right upper lobe pneumonia is common, especially when the fistula presents in older infants and children. In babies, a tube placed in the oesophagus with its external end under water may demonstrate bubbles of air. The fistula can be visualised by a prone tube oesophagogram: with the infant lying prone and a tube positioned in the distal oesophagus contrast is gradually injected as the tube is withdrawn (Fig. 29.49). The fistula can be confirmed by bronchoscopy. Treatment is to divide the fistula, which is best approached through a low cervical incision rather than a thoracotomy (Crabbe et al. 1996). Associated gastro-oesophageal reflux is common.

Laryngo-tracheo-oesophageal cleft

In this malformation, there is incomplete separation of the trachea and oesophagus. It can be associated with various other congenital anomalies, including oesophageal atresia and anorectal malformations. Clefts may be limited to the larynx and cricoid or involve the trachea. Recognising the disorder while intubating a baby with respiratory problems soon after birth is not easy. Difficulty in ventilating the infant may provide a clue. Any doubt about the anatomy of the posterior aspect of the larynx should prompt a detailed laryngoscopy, which will reveal whether it is cleft. Symptomatic or major clefts require surgical repair (Corbally 1993). Treatment of the condition is often difficult and the longer term problems of major clefts can be formidable.

Oesophageal perforation

Iatrogenic perforation of the upper oesophagus from the attempted passage of a nasogastric or endotracheal tube in a premature baby is rare (Krasna et al. 1987). It results in respiratory distress and feeding difficulties. A chest radiograph typically shows a right-sided pneumothorax or a pneumomediastinum (Fig. 29.50). A water-soluble contrast swallow helps to confirm the diagnosis, localise the perforation and direct treatment. Conservative management with chest tube drainage, antibiotics and parenteral nutrition is usually successful. Surgery is rarely required. Spontaneous rupture of the oesophagus in the neonate is extremely rare.

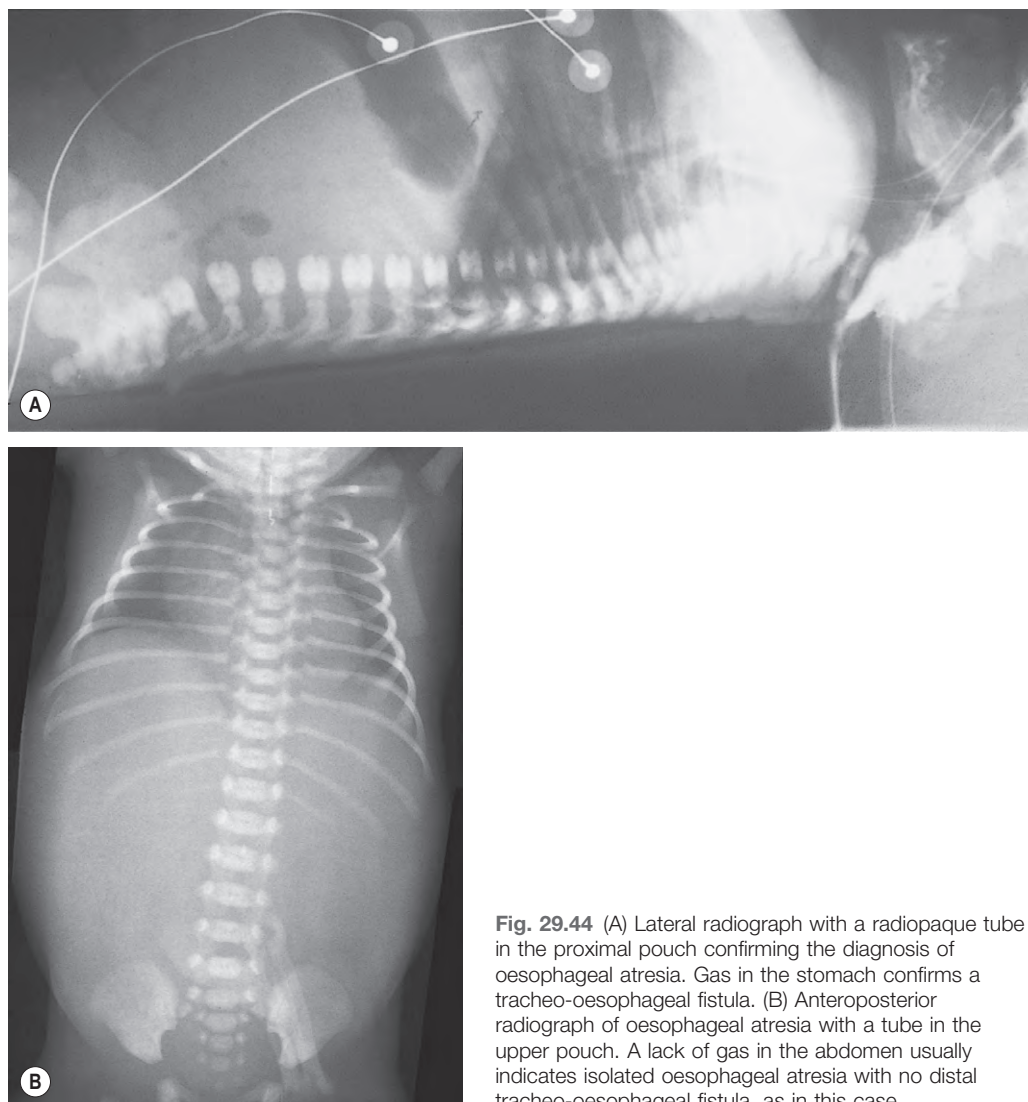

Fig. 29.44 (A) Lateral radiograph with a radiopaque tube in the proximal pouch confirming the diagnosis of oesophageal atresia. Gas in the stomach confirms a tracheo-oesophageal fistula. (B) Anteroposterior radiograph of oesophageal atresia with a tube in the upper pouch. A lack of gas in the abdomen usually indicates isolated oesophageal atresia with no distal tracheo-oesophageal fistula, as in this case.

Fig. 29.45 Tracheoscopy in a baby with oesophageal atresia showing the site of a distal tracheo-oesophageal fistula just above the carina. The left main bronchus is partially collapsed from bronchomalacia.

Hypertrophic pyloric stenosis

In hypertrophic pyloric stenosis (HPS) the pylorus is increased in length and diameter as a result of hypertrophy and hyperplasia of the circular muscle layer. This causes projectile vomiting, typically between 2 and 8 weeks of age. The incidence of HPS in the UK is approximately 3:1000 live births but regional and temporal variations are well recognised. Boys are affected four times more often than girls. Occasionally, HPS is seen in a premature neonate ([Tack et al. 1988](#)) and it has even been described in the fetus. However, HPS is fundamentally an acquired condition. One ultrasound study of asymptomatic newborns failed to show any pyloric abnormality in those babies who subsequently developed HPS ([Rollins et al. 1989](#)). Its exact cause remains uncertain. Various neural and histochemical changes have been described in the pylorus in HPS but whether these are cause or effect is not clear. Infants born with oesophageal atresia are at increased risk, as are premature babies fed through a transpyloric tube ([Evans 1982](#)). A genetic predisposition is apparent in some families.

Typically, the baby feeds hungrily and vomits toward the end of a feed. The vomit is non-bilious but may be blood-stained if there is an associated oesophagitis. Some affected infants are mildly

Fig. 29.46 Radiograph of a baby who is ventilated (endotracheal tube visible) and who has an oesophageal atresia (Replogle tube seen in the upper thorax) and also a tracheo-oesophageal fistula with a markedly dilated stomach.

Fig. 29.47 Radiograph of the same baby as in Fig. 29.46, taken 3 hours later, showing a gross pneumoperitoneum implying gastric rupture.

jaundiced because of an unconjugated hyperbilirubinaemia. Electrolyte abnormalities are common – characteristically, a hypochlo-raemic alkalosis (Touloukian and Higgins 1983). This disturbance may be severe and must be adequately corrected before surgery. Crystalloid solutions containing 0.45% saline and 5% dextrose with 20 mmol/l potassium chloride are useful. Blood glucose should be monitored.

The diagnosis of HPS is made by feeling the hypertrophied pyloric muscle (similar to an olive) while the baby's abdominal muscles are relaxed, such as during a test feed. Gastric peristalsis is often visible. If doubt remains, an ultrasound scan by an experienced sonographer is helpful (Blumhagen et al. 1988); the pyloric muscle is usually 3–4 mm thick and the pyloric length and diameter are increased (Fig. 29.51). Contrast studies are rarely necessary.

The treatment of HPS is by Ramstedt's pyloromyotomy (Fig. 29.52). This can be performed through a transverse upper abdominal incision, a circum-umbilical incision (Fig. 29.53) or laparoscopically. Feeding can be reintroduced within 24 hours of surgery. Minor, transient postoperative vomiting is common. Persistent vomiting is unusual and most often due to associated gastro-oesophageal reflux. Complications of pyloromyotomy, which include incomplete myotomy, duodenal perforation, haemorrhage, wound infection, wound dehiscence and incisional hernia, are rare (Zeidan et al. 1988). There are almost no significant long-term sequelae after a successful pyloromyotomy.

Fig. 29.48 Cervical oesophagostomy. This allows sham feeding.

Pyloric atresia

Pyloric atresia is rare and causes congenital gastric outlet obstruction. The stomach is distended and an abdominal radiograph shows a gasless abdomen beyond the pylorus (Fig. 29.54). Treatment is surgical. The condition is familial in some cases. Associations with

epidermolysis bullosa and multiple intestinal atresias are well described (Okoye et al. 2000).

Gastric volvulus

Gastric volvulus is a rare, potentially life-threatening condition caused by abnormal rotation of the stomach about its axis resulting in a strangulating obstruction. Most instances of gastric volvulus in the newborn are associated with a diaphragmatic defect and/or deficient ligamentous attachments of the stomach (Stringer 2003). Vomiting, haematemesis and respiratory distress are the dominant symptoms. A distended stomach in an abnormal position on a plain abdominal or chest radiograph should raise the possibility of gastric volvulus. Contrast studies clarify the anatomy. If possible, the stomach should be decompressed by the gentle passage of a nasogastric tube. At surgery, the volvulus is reduced, the stomach is fixed and any associated diaphragmatic defect is repaired.

Duodenum and small bowel

Duodenal obstruction in the neonate may be intrinsic or extrinsic or occasionally combined.

Duodenal atresia and stenosis

Intrinsic obstruction may be secondary to duodenal atresia, where there is either a gap between the duodenal segments (often with

Fig. 29.55 Double bubble of duodenal atresia. Air has been injected through the nasogastric tube to highlight the anatomy.

interposed pancreas) or an intact duodenal membrane with continuity of the duodenal wall, or duodenal stenosis, typically with a perforated duodenal web. Intrinsic duodenal obstruction affects approximately 1:6000 live births. Additional anomalies may include intestinal malrotation and, in one-third of patients, Down syndrome. Whether the atresia is due to failure of recanalisation of the embryonic duodenum or to a later intrauterine event is not clear. The obstruction usually occurs in the region of the ampulla of Vater. Anomalies of the distal bile duct explain why, on rare occasions, an infant may have bile-stained vomiting and yet pass normal-coloured meconium (Astley 1969).

The frequent occurrence of polyhydramnios often results in duodenal atresia being detected by prenatal ultrasound (Gee and Abdulla 1978). The characteristic 'double bubble' may be seen only intermittently because of fetal vomiting. Prematurity is common.

Postnatally, duodenal atresia presents with bile-stained vomiting within hours of birth. In 20% of cases the obstruction is proximal to the common bile duct opening in the duodenum and the vomit is non-bilious. Duodenal stenosis causes partial obstruction and may not present during the neonatal period. Examination of the baby may show a distended stomach. A plain radiograph of the abdomen demonstrates the characteristic 'double bubble' sign of gas in the distended stomach and duodenum. This appearance is highlighted if the stomach is first aspirated via a nasogastric tube and 50 ml of air is instilled (Fig. 29.55). In most atresias there is no distal intestinal gas but occasionally a small amount of distal bowel gas may be seen if there is a Y-shaped termination of the common bile duct with limbs above and below the atresia. Significant amounts of distal gas with a distended stomach and duodenum should suggest the possibility of duodenal stenosis or intestinal malrotation and volvulus.

Fig. 29.56 Intestinal malrotation. The classical type of intestinal malrotation predisposes to midgut volvulus.

Management consists of nasogastric decompression, correction of any metabolic alkalosis or electrolyte imbalance, and early surgery. An echocardiogram should be performed in babies with Down syndrome. At operation, the duodenum proximal to the site of atresia is anastomosed to the distal duodenum (duodeno-duodenostomy). Care must be taken not to damage the termination of the common bile duct. Because of the chronic nature of the obstruction, it may take a week or more before gastroduodenal function recovers sufficiently for the baby to tolerate full enteral feeding. Temporary parenteral nutrition is usually required. The outcome of intrinsic duodenal obstruction is related to associated anomalies, since the condition itself can be successfully corrected by surgery.

Intestinal malrotation

Unlike most cases of intrinsic duodenal obstruction, extrinsic obstruction due to intestinal malrotation with volvulus may be intermittent and incomplete and can present at any age. Boys are affected more often than girls. In classical intestinal malrotation, the midgut fails to complete its normal rotational development; the duodenojejunal flexure comes to lie on the right of the midline and the caecum is free-floating in the upper abdomen (Fig. 29.56). Consequently, the base of the small bowel mesentery, which extends between these two points, is a narrow pedicle. This predisposes to midgut volvulus around the superior mesenteric vessels, which can lead to fatal midgut strangulation. Most patients with midgut volvulus present during the first month of life with bilious vomiting. Intestinal strangulation manifests as abdominal distension and rectal bleeding progressing to hypovolaemic shock.

Fig. 29.57 Intestinal malrotation with neonatal midgut volvulus. The abdomen is virtually gasless beyond the distended stomach and duodenum.

Because the obstruction may be intermittent and incomplete, the diagnosis may be delayed. While a plain abdominal radiograph may show an abnormal distribution of bowel gas, there is no single characteristic picture. The small bowel may be distributed more on the right and large bowel on the left of the abdomen. Alternatively, there may be a 'double bubble' of acute duodenal obstruction with a relatively gasless abdomen (Fig. 29.57). Any infant presenting with bile-stained vomiting should have an urgent upper gastrointestinal contrast study if malrotation cannot be excluded (Figs 29.58 and 29.59). Colour Doppler imaging often demonstrates an abnormal relationship of the superior mesenteric artery and vein as a result of the malrotation (Pracros et al. 1992). A barium enema is less reliable in diagnosis but may confirm the abnormal position of the caecum.

Intestinal malrotation may be found in association with other congenital anomalies including congenital diaphragmatic hernia, abdominal wall defects, small bowel atresia, Hirschsprung disease, situs inversus, polysplenia and biliary atresia (Filston and Kirks 1981).

Surgery is mandatory for classical intestinal malrotation, even if the abnormality is diagnosed incidentally. This is because of the risk of midgut strangulation. Lesser degrees of intestinal malrotation rarely require surgery. The operation for classical intestinal malrotation is known as Ladd's procedure. It involves division of peritoneal bands extending from the caecum across the duodenum, broadening the base of the small bowel mesentery, placing the small bowel on the right of the abdomen and the colon on the left, and appendectomy. Subsequent peritoneal adhesions stabilise the gut in a position of non-rotation, thereby reducing the likelihood of volvulus. In cases where there is a volvulus at the time of surgery, this must be promptly untwisted and as much viable bowel as possible preserved. A repeat laparotomy performed 24 hours later may be helpful if bowel viability is initially uncertain.

Fig. 29.59 Lateral radiograph showing barium passing down the duodenum and forming a corkscrew (arrows) configuration due to a midgut volvulus.

Jejunal and ileal atresia

Atresia of the jejunum or ileum is most often caused by a late gestational interruption to the blood supply of the fetal gut. This was shown experimentally by Louw (1959). This intrauterine mesenteric vascular accident may arise from intestinal volvulus (associated with midgut malrotation, cystic fibrosis (CF) or a duplication cyst), intussusception, the action of vasoconstrictor drugs such as cocaine or constriction of the mesentery in a tight abdominal wall defect.

Fig. 29.60 Classification of intestinal atresia. Type I, membranous atresia with intact bowel wall and mesentery; type II, two atretic blind ends connected by a fibrous cord with an intact mesentery; type IIIa, two ends of atretic bowel separated by a V-shaped mesenteric defect; type IIIb, 'apple-peel' deformity; type IV, multiple atresias ('string of sausages'). (Reproduced from Grosfeld et al. (1979) with permission.)

A segment of small bowel is infarcted and reabsorbed, leaving a jejunal or ileal atresia. Multiple intestinal atresias are rare, may be familial and probably have a different pathogenesis (Noblett 1969; Puri and Fujimoto 1988).

Jejunioileal atresias can be classified into four types (Grosfeld et al. 1979) (Fig. 29.60). Type III is the commonest and is typically associated with a shorter bowel length. Type IIIb is known as an apple-peel deformity and consists of a proximal jejunal atresia, a wide mesenteric gap and a distal small bowel segment coiled around a marginal artery (Fig. 29.61). This classification is related more to the management and complications of intestinal atresia than to their presenting features.

Except for a lower mean birthweight, the baby with small bowel atresia often appears normal. There may be a history of maternal polyhydramnios or, rarely, dilated fetal bowel may have been detected by prenatal sonography (Richards and Holmes 1995). Vomiting begins within a day or two of birth – the higher the atresia, the earlier the vomiting. Bilious vomiting is a typical feature of jejunal atresia and abdominal distension is often prominent with ileal atresia. The baby fails to pass normal meconium. Inspection of the baby's abdomen may show distended bowel loops. A plain abdominal radiograph demonstrates the characteristic picture of intestinal obstruction with dilated loops of bowel and multiple fluid levels (Figs 29.62 and 29.63). The more distal the atresia, the

Fig. 29.61 Apple-peel atresia. The proximal bowel is dilated and congested.

Fig. 29.62 Anteroposterior radiograph showing dilated bowel and fluid levels, indicating a proximal jejunal obstruction.

Fig. 29.63 (A) Supine radiograph showing ladder pattern of obstructed small bowel. (B) Erect film of the same baby showing dilated bowel with fluid levels indicating an ileal obstruction.

greater the number of distended bowel loops. Peritoneal calcification is a sign of intrauterine perforation. In a stable infant, a contrast enema may be required to clarify the cause of a distal bowel obstruction. Most infants with jejunoileal atresia have a microcolon.

After resuscitation, nasogastric decompression and any necessary urgent investigations, the baby should undergo surgery. At laparotomy the bowel distal to an obvious atresia must be examined carefully to exclude further atresias. Infants with type I and II atresias require resection of a short segment of dilated proximal bowel and an end-to-end anastomosis of the gut. Complications are infrequent and their long-term prognosis is good. Infants with type III defects require similar surgery but, because of the prenatal bowel loss, early postoperative digestive problems are common and parenteral nutrition is usually needed. Modified feeds may be necessary to optimise nutrition. An anastomotic leak or stenosis is rare but episodes of functional intestinal obstruction are common during the early postoperative period. Despite this, adaptation occurs rapidly and long-term parenteral feeding is seldom required. In babies with multiple intestinal atresias, several anastomoses may be needed to preserve the maximum length of bowel. A sweat test and DNA mutational analysis are undertaken to exclude CF in infants with jejunoileal atresia.

Infants with a short gut require long-term follow-up to monitor their growth and development, address any nutritional deficiencies and detect and treat potential complications such as gallstones and late anastomotic ulceration.

Meconium ileus

In this condition, obstruction of the small bowel lumen is caused by highly viscid meconium containing excess protein. CF is almost invariably the underlying cause, although exceptions do occur (Shigemoto et al. 1978). Approximately 10–15% of infants with CF present in this way.

Meconium ileus may be uncomplicated or complicated. In uncomplicated cases, there is small bowel obstruction, usually in the distal ileum. The proximal bowel is dilated and the distal small bowel is narrow and packed with grey-coloured meconium pellets. The unused colon is a narrow microcolon. Complicated meconium ileus is caused by a volvulus of meconium-laden bowel in the fetus. This may result in intestinal perforation, meconium peritonitis and meconium pseudocyst formation or an ileal atresia.

The neonate with meconium ileus usually has marked abdominal distension soon after birth, often accompanied by visible and palpable loops of bowel. There may be a palpable mobile abdominal mass.

The baby does not pass meconium, although small plugs or pellets of pale material may be passed. Vomiting becomes progressively worse and bile-stained.

There may be a family history of CF or prenatal genetic analysis may already have been performed. Hyperechogenic fetal bowel (see above) or meconium peritonitis may have been identified by prenatal sonography. Postnatally, CF mutation analysis and sweat testing will confirm the aetiology. There is no clear-cut genotype correlation with meconium ileus but an association with delta F508 and G542X mutations has been reported (Feingold and Guilloud-Bataille 1999).

A plain abdominal radiograph shows marked bowel distension. Fluid levels are uncommon because of the viscid meconium. A 'soap bubble' appearance, caused by the admixture of air and viscid meconium, may be noted (Fig. 29.64) but this is not pathognomonic for meconium ileus. In complicated cases intraperitoneal calcification or a cystic mass may be visible.

Fig. 29.64 Abdominal radiograph of a baby with meconium ileus. Note the lack of fluid levels and the 'soap bubble' appearance in the right lower quadrant.

Fig. 29.65 A patient with complicated meconium ileus. Note the marked abdominal distension and discoloration of the anterior abdominal wall.

Neonates with complicated meconium ileus require surgery (Fig. 29.65). In uncomplicated cases, an isotonic contrast enema is diagnostic, showing an unused microcolon (Fig. 29.66) and inspissated meconium in the terminal ileum. Prophylactic antibiotics are advisable prior to giving the enema. Occasionally, this same appearance

Fig. 29.66 Contrast enema showing a microcolon and dilated loops of proximal small bowel in meconium ileus.

is mimicked by total colonic aganglionosis. Passage of contrast into dilated proximal bowel confirms its patency. Once this is determined, a therapeutic enema can be used (**Fig. 29.67**). Hyperosmolar solutions, such as dilute Gastrografin, draw fluid into the lumen of the gut, making the meconium less tenacious and encouraging its evacuation (**Noblett 1969**). Additional intravenous fluids are required to compensate for this fluid loss. The enema may need to be repeated at daily intervals over the next few days before normal bowel movements are achieved (**Boyd et al. 1988**).

Non-operative management of uncomplicated meconium ileus is successful in about 50% of cases but it carries a risk of intestinal perforation. The presence of complicated meconium ileus precludes the use of a therapeutic enema and is an indication for surgery. Similarly, infants not responding to conservative management require operation. Various surgical procedures are used to treat meconium ileus, including intestinal resection and temporary stoma formation, resection and primary anastomosis and, in uncomplicated cases, enterotomy and irrigation of the bowel (**Fig. 29.68**).

Survival rates for infants with meconium ileus have improved progressively. Recent reports document survival rates of 90% for complicated meconium ileus and a higher figure for uncomplicated cases (**Rescorla and Grosfeld 1993; Mushtaq et al. 1998**). Advances in the overall management of CF have contributed to this success. Infants with CF who present with meconium ileus have a relatively good long-term prognosis (**Coutts et al. 1997**).

Fig. 29.67 Gastrografin enema filling the caecum and terminal ileum and outlining plugs of meconium in the distal ileum in a baby with meconium ileus.

Fig. 29.68 Enterotomy in meconium ileus. The thick, tenacious meconium is milked out of the bowel lumen after irrigation.

Alimentary tract duplications

Alimentary tract duplications are rare congenital malformations. Most are single, cystic lesions but some are tubular, running parallel to the gut. Typically, they are lined by alimentary tract mucosa and share a common smooth-muscle wall and blood supply with the adjacent gut. Some communicate directly with the lumen of the native alimentary tract. About 50% of duplications occur in the midgut and 35% in the foregut (**Fig. 29.69**) (**Stringer et al. 1995b**).

One-third of duplication cysts present in the neonate with symptoms of obstruction, bleeding or inflammation. Some only become apparent during investigation of more severe congenital anomalies

Fig. 29.69 Distribution of alimentary tract duplications. (Reproduced from *Stringer et al. (1995b)*.)

such as anorectal malformations, oesophageal atresia or bladder/cloacal exstrophy. Additional congenital abnormalities are common. Examples include exstrophy or myelomeningocele with hindgut duplication, intestinal malrotation with midgut lesions, and oesophageal atresia with foregut duplication. Some duplications, particularly foregut lesions, are associated with vertebral anomalies and even intraspinal pathology. Heterotopic gastric mucosa is found in one-third of duplications and may cause ulceration and bleeding.

Paraesophageal cysts may present with respiratory symptoms or be noticed first on a chest radiograph (Fig. 29.70). Thoracoabdominal duplications have the greatest potential for complications; they usually lie to the right of the oesophagus in the posterior mediastinum and may communicate distally, through the diaphragm, with the upper gastrointestinal tract. Intestinal duplications most often present with bowel obstruction (from local compression, volvulus or intussusception). An increasing proportion of duplication cysts are discovered during prenatal ultrasound scans.

Duplications are best managed by early complete excision to avoid complications, which include a small potential for malignant degeneration in adult life.

Other causes of neonatal small bowel obstruction

There are several other causes of intestinal obstruction in the newborn. Necrotising enterocolitis (pp. 708–717) and an

Fig. 29.70 Computed tomography scan of the thoracic inlet in an infant with a paraesophageal duplication cyst (arrows) causing tracheal deviation and respiratory symptoms.

Fig. 29.71 Intraoperative picture of a baby with Hirschsprung disease showing the calibre change from aganglionic to ganglionic bowel.

incarcerated inguinal hernia (see below) are relatively common causes. Rarer conditions include neonatal acute appendicitis, segmental small bowel volvulus (not due to midgut malrotation, CF or duplication cyst), an adhesion band connected to a vitellointestinal remnant, distal small bowel obstruction from inspissated formula milk curds (Cook and Rickham 1969) and pseudo-obstruction from intestinal neuropathy or myopathy. Neonatal intussusception may mimic necrotising enterocolitis (Wang et al. 1998). An abdominal ultrasound scan and plain abdominal radiographs are often helpful in diagnosing these conditions.

Large bowel

Hirschsprung disease

In a neonate with delayed passage of meconium, increasing abdominal distension and bilious vomiting, Hirschsprung disease must be excluded (Stringer 1999).

Hirschsprung disease is characterised by a congenital absence of intramural ganglion cells in the rectum. This aganglionosis and the presence of hypertrophied nerve trunks lead to a tonic contraction of the involved segment of gut, which causes a functional intestinal obstruction (Fig. 29.71). The abnormalities of innervation extend into the proximal bowel to a variable degree.

Harald Hirschsprung, a Danish paediatrician, provided the first comprehensive account of the disease in 1887, although he wrongly believed that the proximal dilated colon was the cause of the condition (Hirschsprung 1887).

The aganglionosis is restricted to the rectum and sigmoid colon in 75% of patients (short-segment Hirschsprung disease), extends to the splenic flexure or transverse colon in 15% (long-segment Hirschsprung's disease) and along the entire colon and a variable length of terminal ileum in 8% (total colonic aganglionosis). Rarely, ganglion cells are absent as far proximally as the jejunum or duodenum.

Enteric ganglion cells are derived from vagal neural crest cells that migrate down the gut to the rectum in the embryo. Failure of this process is understood to be the cause of Hirschsprung disease. The incidence of the condition is about 1:5000 live births, with a male to female ratio of 4:1; this sex difference is less marked in longer segment disease.

Numerous conditions are associated with Hirschsprung disease. The most consistent association is with Down syndrome but various other chromosomal abnormalities and syndromes are recognised (Shaw et al. 1996). Cardiac, genitourinary, central nervous system and gastrointestinal abnormalities are each recorded in about 5% of patients. Links with congenital central hypoventilation (Croaker et al. 1998), Waardenburg syndrome (Moore and Johnson 1998), Mowat–Wilson syndrome (Mowat et al. 2003), multiple endocrine neoplasia and intestinal neuronal dysplasia are well described.

Advances in molecular genetics have confirmed that Hirschsprung disease is a genetic disorder (Kusafuka and Puri 1998). Most cases are sporadic but autosomal dominant, autosomal recessive and polygenic patterns of inheritance within families have been reported. Mutations in the *RET* proto-oncogene region of chromosome 10 are known to account for many cases. Other gene defects causing familial Hirschsprung disease have been mapped to the endothelin-B receptor gene on chromosome 13. The association of Hirschsprung disease with Down syndrome, chromosomal anomalies and genetically determined syndromes emphasises the genetic nature of the condition.

Hirschsprung disease typically presents during the neonatal period. Delayed passage of meconium is the cardinal clinical feature and is typically accompanied by progressive abdominal distension, reluctance to feed and vomiting, which is often bilious. Over 95% of healthy term infants pass their first stool within 24 hours of birth (Sherry and Kramer 1955). Delayed passage of meconium beyond 48 hours in a term infant should suggest the possibility of Hirschsprung disease. Delayed passage of meconium is normal in premature infants (Weaver and Lucas 1993) and this is therefore a less reliable feature of Hirschsprung disease in this group.

Rectal examination typically reveals a tightly contracted anorectum and withdrawal of the finger may be followed by an explosive discharge of stool and gas. In some cases, this induces a temporary remission but the baby continues to have problems with constipation. If the obstruction is not relieved the infant is at risk of intestinal perforation, enterocolitis and death.

Hirschsprung's enterocolitis is a serious and potentially fatal complication. It is characterised by marked abdominal distension, explosive diarrhoea, vomiting and fever. The clinical and radiological picture may be indistinguishable from necrotising enterocolitis. Obstruction, infection (e.g. *Clostridium difficile*) and impaired mucosal immunity are important predisposing factors. Bowel decompression by repeated rectal lavage with warm normal saline is the usual first-line treatment. Intravenous broad-spectrum antibiotics are given initially but ceased once washouts are established and the child is feeding normally.

Fig. 29.72 Intestinal obstruction with an absence of gas in the rectum in a baby with Hirschsprung disease.

Histological examination of an adequate rectal biopsy by an experienced pathologist is the gold standard in the diagnosis of Hirschsprung disease. The main diagnostic tools are described below.

Radiology

Plain abdominal radiographs characteristically show multiple dilated loops of bowel with an absent rectal gas shadow (Fig. 29.72) but the latter is not specific for Hirschsprung disease. In infants with enterocolitis, thickening of the bowel wall, mucosal irregularity and/or a grossly dilated colon may be evident. A contrast enema performed by an experienced radiologist using an isotonic water-soluble contrast medium is often used to diagnose Hirschsprung disease but the results are not always reliable. Typically, contrast outlines a narrow distal segment of rectum and colon, a cone-shaped transition zone and a proximal dilated colon (Fig. 29.73). However, the cone is not necessarily the site of the transition zone between abnormal and healthy bowel.

Anorectal manometry

The resting pressure within the anal canal and lower rectum is raised and there is no anal relaxation in response to a distending stimulus in the rectum (absent rectoanal inhibitory reflex). Misleading results may occur and this technique is now used infrequently.

Rectal biopsy

A suction rectal biopsy is taken from above the anal canal (usually 2–4 cm from the anal verge) and must contain adequate amounts of submucosa, be appropriately oriented and sectioned, and be examined by an experienced histopathologist. Diagnosis rests on the absence of ganglion cells, the presence of thickened nerve trunks and a marked increase in acetylcholinesterase activity in the hypertrophied nerve bundles.

Initial treatment of Hirschsprung disease consists of decompressing the dilated proximal (ganglionic) bowel by rectal washouts using small volumes of warm saline (Fig. 29.74). Initially, this may

Fig. 29.73 Barium enema showing a 'transition zone' at the junction of the descending and colon (arrow). The actual transition zone was found to be proximal to this site.

be required twice daily but, with time, once a day is sufficient. If this fails to decompress the bowel then a stoma is necessary. The aim of definitive surgery for Hirschsprung disease is to resect the aganglionic bowel and to join healthy ganglionic proximal bowel to the anorectal stump.

Various techniques are described (e.g. Duhamel's, Soave's and Swenson's operations), and this implies that none is perfect. In the majority of infants, surgical correction is now performed as a single-stage procedure (primary pull-through) rather than the traditional approach of proximal stoma formation, definitive surgery and subsequent stoma closure. Recent developments include laparoscopically assisted procedures and transanal operations, which obviate the need for an abdominal incision in short-segment disease. Primary pull-through procedures are best avoided if the colon cannot be adequately decompressed by rectal washouts (and this includes most cases with total colonic aganglionosis), if enterocolitis cannot be rapidly controlled by medical treatment or if intestinal perforation has occurred.

Most patients can expect good long-term bowel function after definitive surgery for Hirschsprung disease. However, a significant proportion continue to have problems despite a technically adequate pull-through with fully ganglionic bowel. Potential long-term problems include enterocolitis, constipation and faecal incontinence. Long-term bowel function is influenced by early surgical complications, bowel training and the social background and intelligence of the child. In most series, about 75% of patients will achieve good bowel control as they reach adulthood (Engum and Grosfeld 1998). A UK support group for parents and families is called the Hirschsprung's and Motility Disorders Support Network (see Weblinks, below). Down syndrome has a major adverse impact on the acquisition of faecal continence in Hirschsprung disease.

The risk of disease in future offspring depends on the sex of the affected individual and the extent of the aganglionosis; increasingly,

Fig. 29.74 Rectal washouts in Hirschsprung disease. The mother is being supervised by a specialist nurse.

families of patients with Hirschsprung disease are routinely referred for genetic review (Badner et al. 1990).

Anorectal malformations

Anorectal malformations encompass a wide spectrum of congenital defects ranging from a minor malposition of the anus to complete agenesis of the anorectum. Classification of these anomalies is difficult but Pena (1995) has suggested a practical approach based on gender and differences in treatment and prognosis, although the Krickenbach classification is now being advocated (Holschneider et al. 2005). The common types of malformation are listed in Table 29.27 and shown in Figure 29.75.

In boys, an imperforate anus with the rectum terminating as a rectourethral fistula is the most frequent malformation. Next commonest is a low termination of the rectum and a perineal fistula. In girls, an anterior anus or perineal fistula or an imperforate anus with a rectovestibular fistula are the commonest lesions. Cloacal malformations account for about 10% of female defects.

Fig. 29.75 Commoner varieties of anorectal malformations. (A) Perineal fistula in a boy; (B) rectourethral fistula in a boy; (C) rectovestibular fistula; (D) anterior stenotic anus in a girl; (E) cloacal anomaly.

Table 29.27 Types of anorectal malformation: Krickenbeck classification (Holschneider et al. 2005)

MAJOR CLINICAL GROUPS	RARE/REGIONAL VARIETIES
Perineal (cutaneous) fistula	Pouch colon
Rectourethral fistula: (a) prostatic or (b) bulbar	Rectal atresia or stenosis
Rectovesical	Rectovaginal
Vestibular	'H' fistula
Cloaca: (a) <3 cm or (b) >3 cm common channel	

The incidence of anorectal malformations is around 1:4000–5000 live births. The cause of these defects is unknown. Most are sporadic. Traditionally, anorectal malformations have been understood to arise as a result of abnormal partitioning of the embryonic cloaca by the caudal descent of the urorectal septum, but this view is almost certainly too simplistic (Kluth and Lambrecht 1997).

At least 40% of affected patients have additional congenital defects. This figure is higher in patients with high anorectal

malformations (Rintala et al. 1991). Associated conditions include the following:

- **Genitourinary:** these are the commonest. Examples include absent, dysplastic, cross-fused or horseshoe kidneys, vesicoureteric reflux, hydronephrosis, hypospadias, bifid scrotum and cryptorchidism. Girls with cloacal anomalies may have vaginal and uterine malformations.
- **Skeletal:** lumbosacral vertebral anomalies are most common. Sacral defects are more frequent and more severe with high malformations. The absence of two or more sacral vertebrae is associated with a poor functional outcome (Rintala et al. 1991).
- **Spinal cord:** a range of spinal cord anomalies have been described since the advent of magnetic resonance imaging.
- **Gastrointestinal:** the best known association is with oesophageal atresia as part of the VACTERL complex (see above).
- **Cardiovascular:** various abnormalities may coexist.
- **Syndromes:** the commonest is the VACTERL association. Another example is the Currarino triad due to an autosomal dominant gene on chromosome 7, manifesting as partial sacral agenesis, anal stenosis and a presacral mass (e.g. meningocele or sacrococcygeal teratoma) (Currarino et al. 1981). Trisomy 21 is a recognised association in anorectal malformations and may involve a pure atresia rather than a fistula (Fig. 29.76).

Early diagnosis is important to avoid complications such as intestinal perforation and urinary tract infection. All infants should be

Fig. 29.76 A child with Down syndrome and a rectal atresia. An imperforate anus is visible, as is a large mongolian blue spot.

examined thoroughly, including the spine and genitalia. In most cases, a detailed inspection of the perineum can distinguish low and high malformations.

In boys with low lesions, the anus is imperforate or appears abnormal. There is a single abnormal opening on the perineum or a track may be seen running along the midline raphe to the scrotum (Fig. 29.77). Boys with low lesions have a well-developed buttock cleft and anal dimple, good sphincter muscles and a normal sacrum. With higher lesions in boys, no perineal orifice is seen (Fig. 29.78) but meconium or bubbles may appear in the urine. In such cases, the pelvic and perineal muscles are less well developed and a sacral defect may be evident.

In normal girls, the anus is positioned midway between the posterior fourchette and the tip of the coccyx. A stenotic anterior anus (Fig. 29.79) is easily overlooked in the newborn and may not present until later, with severe constipation. In girls, it is important to count the number of perineal orifices. If only the vagina and urethra are visible, then the infant probably has a rectovestibular malformation in which the rectum opens immediately in front of the posterior fourchette (Fig. 29.80). Meconium is often passed through the fistula after birth. If there is only one perineal opening, then the baby has a cloacal malformation characterised by the confluence of rectum, vagina and urethra into a single common channel (Fig. 29.81). Neonatal hydrocolpos and urinary obstruction may complicate this anomaly.

If the clinical picture is unclear, a lateral prone radiograph at about 24 hours of age with the baby's pelvis elevated helps to distinguish high and low lesions. The anal dimple must be marked with a radiopaque marker (Fig. 29.82). The distance between the rectal termination and the anal skin can be measured. If this radiograph is performed too early, it may falsely suggest a high lesion because the gas has not yet reached the point of obstruction. The presence of air in the bladder is evidence of a rectourinary fistula.

Other useful investigations in a neonate with an anorectal malformation include lumbosacral and chest radiographs, a urinary tract ultrasound scan, echocardiography and, in selected cases, a karyotype.

Most low lesions can be successfully treated by an anoplasty soon after birth. Temporary use of an anal dilator is often needed.

Fig. 29.77 Low anorectal anomaly. A perineal fistula with meconium seen at base of scrotum but also pearls of meconium seen tracking along the midline scrotal raphe on to the base of the penis.

Fig. 29.78 Imperforate anus in a boy with a rectourethral fistula.

Fig. 29.79 An anterior stenotic anus in a girl. Note how narrow the perineal body is.

Constipation is a common problem but, provided this is managed aggressively, good bowel control can be achieved (Rintala *et al.* 1997). Higher malformations are usually treated by a diverting, proximal colostomy soon after birth and definitive repair of the malformation a few months later once the anatomy of the malformation has been defined and the infant is thriving. The posterior sagittal anorectoplasty is the current standard reconstructive operative procedure (Pena 1995); however, a laparoscopic approach to divide the fistula and then pull the bowel through a much smaller perineal incision is gaining popularity (El-Debeiky *et al.* 2009). Outcome in terms of constipation, soiling and faecal continence are affected by the type of anorectal malformation (many high lesions are associated with some faecal incontinence), the presence of a sacral defect and the method and timing of surgery. Many children require considerable help in achieving social continence and coping with psychosocial sequelae (Ludman 1998).

Colonic atresia

This is a rare form of atresia, accounting for only 5% of intestinal atresias. It may be associated with limb anomalies, abdominal wall defects, Hirschsprung disease or other atresias. Presentation is that of a low intestinal obstruction. The baby develops abdominal distension and progressive vomiting, and fails to pass meconium. An abdominal radiograph shows evidence of a distal bowel obstruction and a contrast enema demonstrates the level of the atresia. Staged surgery is often required, with initial relief of the obstruction by colostomy, followed later by large bowel anastomosis.

Fig. 29.80 A rectovestibular fistula demonstrated with a cannula in the fistula.

Fig. 29.81 A cloacal anomaly with a single perineal orifice only.

Fig. 29.82 Lateral prone radiograph with pelvic elevation at 24–36 hours of age in babies with (A) low and (B) high anorectal malformations. Note the distance between the rectal gas shadow and the anal marker in each case.

Meconium plug obstruction

Meconium plug obstruction occurs most often in the low-birthweight baby who may also be compromised by other problems such as perinatal hypoxia, hypothermia and the effects of medication given to the mother in labour. It can be difficult to achieve a balance between subjecting the baby to potentially unnecessary investigations and overlooking genuine pathology. The main differential diagnosis is between meconium plug obstruction, Hirschsprung disease and CF, all of which can occur in low-birthweight infants. Contrast enema studies in this situation may be misinterpreted as showing evidence of Hirschsprung disease.

In preterm infants, expectant observation is usually the best approach. If abdominal distension is severe, gentle irrigation of the baby's rectum with warm saline usually relieves the obstruction and yields a pale plug of meconium (**Fig. 29.83**). Alternatively, warmed dilute Gastrografin may be instilled into the large bowel via a soft rectal catheter and a radiograph will demonstrate the meconium plug. This procedure often provokes passage of the plug and, once the infant has started passing motions, continuing difficulty is less marked. The infant with a meconium plug must be observed closely and followed up after discharge.

In full-term infants, delay in passage of meconium beyond 48 hours always merits investigation.

Fig. 29.83 Meconium plug.

Fig. 29.84 Contrast enema in a baby with small left-colon syndrome.

Megacystis–microcolon–intestinal hypoperistalsis syndrome

This rare entity, which is commoner in girls, is a form of visceral myopathy causing severe functional intestinal obstruction ([Puri and Tsuji 1992](#)). Intestinal and bladder motility are markedly impaired. Infants also have lax abdominal muscles and incomplete intestinal rotation. Most cases are reliant on long-term parenteral nutrition for survival.

Small left-colon syndrome

This term is used for a transient functional neonatal large bowel obstruction caused by a small-calibre left colon distal to the splenic flexure. It is associated with maternal insulin-dependent diabetes. The degree of obstruction is variable. A contrast enema is diagnostic and often therapeutic (**Fig. 29.84**). Hirschsprung disease must be excluded.

Stomas

An intestinal stoma may be temporarily required in the management of various neonatal surgical conditions, including necrotising enterocolitis, Hirschsprung disease, anorectal malformations,

Fig. 29.85 Prolapse of an ileostomy.

Fig. 29.86 A baby who had a split ileostomy and mucous fistula created for complicated necrotising enterocolitis. The ileostomy has become ischaemic.

intestinal atresia and complicated meconium ileus. Most are colostomies or ileostomies. Potential stoma complications include:

- mechanical, e.g. prolapse, stenosis, retraction – prolapse is more common with a loop stoma (Fig. 29.85)
- leakage and skin excoriation
- fluid and electrolyte losses – especially with small bowel stomas
- nutritional problems
- wound infection, candidiasis
- ischaemia (Fig. 29.86).

Expert surgical nursing care and appropriate stoma appliances are paramount.

Sodium deficiency occurs frequently with neonatal ileostomies or proximal colostomies. Plasma sodium levels are usually normal but urinary sodium concentrations are consistently less than 10 mmol/l, indicating a total body sodium deficit (Bower et al. 1988). A mild metabolic acidosis and growth failure ensue despite a good calorie intake. Before normal growth can be achieved, these babies must have their feeds supplemented with sodium chloride to restore normal urinary sodium excretion.

Anterior abdominal wall defects

Although gastroschisis was recognised as early as 1733 (Calder 1733), only in the last 50 years has it been clearly differentiated from exomphalos. A distinction between these two anterior abdominal wall defects is clinically important, but not all infants fall neatly into one or other category. The prevalence of gastroschisis is about 1:7000 total births (Curry et al. 2000) but there are significant regional variations within the UK and abroad (Stone et al. 1998; Di Tanna et al. 2002). Exomphalos is at least twice as common (Calzolari et al. 1995; Stone et al. 1998). Gastroschisis has become more prevalent in the past 25 years while the frequency of exomphalos has remained much the same. Both sexes are similarly affected. A UK parents support group can be found in the Weblinks section (see below):

- In simple terms, the anterior abdominal wall is formed by four separate embryological folds – cephalic, caudal and lateral – each of which has a splanchnic and somatic component. Failure of union of the cephalic fold results in exomphalos with a sternal/diaphragmatic defect or the pentalogy of Cantrell et al. (1958). Failure of the caudal fold to close results in exomphalos with bladder or cloacal exstrophy. Failure of the lateral folds to close results in exomphalos. The pathogenesis of gastroschisis is less clear. Suggested mechanisms include a local failure of differentiation of mesoderm forming the abdominal wall muscles, rupture of the membrane covering a hernia of the umbilical cord or a vascular insult interfering with the development of the somatopleure at the junction with the body stalk (Curry et al. 2000).
- Prenatal ultrasound is highly sensitive in the diagnosis of anterior abdominal wall defects. Most defects are detectable by 16–20 weeks' gestation and it is usually possible to differentiate between exomphalos and gastroschisis. This is important since exomphalos is frequently associated with chromosomal anomalies (e.g. trisomy 13, 18 and 21) and major congenital heart defects (Gilbert and Nicolaides 1987), indicating the need for fetal karyotyping and echocardiography. Although exomphalos is seen more often than gastroschisis in utero, this relationship is reversed at birth because of fetal deaths and terminations in the exomphalos group. For the same reasons, the observed incidence of additional congenital anomalies in neonates with exomphalos is less than expected. Gastroschisis is rarely associated with aneuploidy.

Exomphalos

This term encompasses a spectrum of abnormalities ranging from a small umbilical defect with gut prolapsing into the cord (a hernia into the cord; Fig. 29.87), through umbilical defects less than 5 cm wide (exomphalos minor; Fig. 29.88) to larger umbilical defects (exomphalos major or giant omphalocele; Fig. 29.89). Bowel and often liver are enclosed within the sac (unless it has ruptured). Since the developing bowel has failed to complete its normal return to the abdominal cavity from the umbilical cord, disorders of intestinal rotation may be found with all these umbilical defects, but classical midgut malrotation is uncommon:

- Urgent surgery is not indicated for the infant with an exomphalos and an intact amniotic sac. Echocardiography, karyotyping and, in selected cases, upper gastrointestinal contrast studies to assess gut rotation should be performed. Blood glucose must be monitored, particularly since

Fig. 29.87 A hernia into the cord containing the caecum and appendix. The infant had no other anomalies.

Fig. 29.88 An exomphalos minor.

Beckwith–Wiedemann syndrome (Ch. 31) may present with exomphalos. Other associations include intestinal atresia or stenosis.

- With a hernia into the cord or exomphalos minor, once the defect has been repaired the long-term outlook is good provided there is no associated syndrome or additional major congenital abnormality.

Fig. 29.89 Exomphalos major containing liver and bowel.

Fig. 29.90 Baby born with a ruptured exomphalos that required application of silo at birth.

- In exomphalos major, reduction of the herniated bowel and liver into the abdominal cavity can be difficult. It may require the surgical application of sterile prosthetic material to the rim of the abdominal wall defect and gradual reduction of the contents of this silo over a period of 7–10 days (staged silo repair; Fig. 29.90). The fascia and skin are repaired as the final procedure. Temporary support with parenteral nutrition is often required. With this technique, potentially serious complications may occur. Consequently, a conservative approach is sometimes used. This involves treating the sac with desiccating antiseptic agents. Mercurochrome is potentially toxic (Fagan et al. 1977) and has been replaced by silver sulfadiazine ointment (Fig. 29.91) or povidone iodine spray. Thyroid function may be disturbed by prolonged use of the latter (Cosman et al. 1988). The sac gradually contracts, leaving a correctable abdominal wall defect.
- Outcome is largely dictated by the severity of associated malformations. In some infants, both the abdominal and thoracic cavities are poorly developed and pulmonary hypoplasia may pose additional problems. A ruptured exomphalos requires urgent surgery (Figs 29.90 and 29.92).

Fig. 29.91 Exomphalos major treated with flamazine. Note the epithelialisation of the sac at its edge.

Fig. 29.92 Same baby as in Fig. 29.84. Radiograph confirmed a severe kyphoscoliosis with poorly developed thoracic and abdominal cavities.

Gastroschisis

In gastroschisis, the bowel prolapses through a defect that is typically just to the right of the umbilicus (Fig. 29.93). Unlike exomphalos, there is no covering membrane. The extent of evisceration is variable but may include stomach, small bowel, colon, and ovary and fallopian tube or testis. Only rarely is the liver involved:

- Young maternal age (median 21 years) is consistently associated with the condition and other maternal risk factors have also been identified (Curry et al. 2000). Infants with gastroschisis are typically of low birthweight (median 2.3 kg) and do not usually have other life-threatening anomalies. Intestinal atresia is found in about 10% of cases (Fig. 29.94) and the bowel in gastroschisis is non-rotated. Rarely the gastroschisis defect narrows before birth, which leads to a potentially devastating outcome due to loss of the herniated bowel (Fig. 29.95).
- The postnatal appearance of the bowel varies from almost normal to a foreshortened, thickened mass covered in a dense fibrin 'peel'. The duration of exposure of the fetal gut to

Fig. 29.93 Gastroschisis. The bowel is matted and has a fibrin peel. Note that the abdominal wall defect is just to the right of the umbilicus.

Fig. 29.94 Intestinal atresia associated with gastroschisis.

amniotic fluid may determine this appearance but clinical and experimental evidence suggests that it is related more to vascular compression of the mesentery of the gut by the edges of the abdominal wall defect.

- Infants with gastroschisis lose fluid and heat readily from the exposed bowel. Immediately after delivery they require intravenous fluids, a nasogastric tube and measures to stabilise and insulate the bowel. Cellophane wrapping ('cling-film') allows the bowel to be inspected and prevents harmful traction on the mesentery (Fig. 29.96). In utero transfer to a centre with obstetric and paediatric surgical services is preferable to postnatal transfer since it facilitates prompt postnatal surgical treatment and enables mother and baby to be together.
- The management of gastroschisis has changed in many centres over the last few years. The standard treatment used to be (and still is for some surgeons) reduction under general anaesthesia, with repair of the defect (primary closure). This

Fig. 29.95 A baby born with a closing gastroschisis. Note the small amount of bowel left, including one ischaemic loop.

Fig. 29.96 The exposed gut can be temporarily insulated and stabilised with a 'cling-film' wrap.

usually leaves a good cosmetic appearance (Fig. 29.97). In cases where the abdominal cavity is not large enough to accommodate the viscera, a staged silo repair (see above) is necessary (Fig. 29.98). Recently, placing the bowel into a preformed silo (Fig. 29.99), with the baby awake on the neonatal unit, has become the alternative choice of treatment (Lansdale et al. 2009). This avoids the neonate requiring a general anaesthetic, prevents the bowel reduction being tight (which avoids the need for postoperative ventilation, with its associated complications) and the bowel contents can be reduced in a controlled manner over a few days. The silo is then removed and the abdomen closed on the unit without general anaesthesia. Occasionally, it is possible to reduce the gastroschisis fully with the baby awake.

- Although 90% or more of affected babies now survive, their postnatal course is often protracted. Full enteral feeding is usually not achieved for about 3 weeks after primary closure and during this period the infant requires total parenteral nutrition with its attendant risks and complications. Babies with gastroschisis often stay in hospital for several weeks. Those with atresias or severe short-gut syndrome may have a

Fig. 29.97 Appearance of the umbilicus after primary repair of gastroschisis.

Fig. 29.98 Gastroschisis with a Prolene silo formed. This will be tucked daily to reduce the bowel into the abdominal cavity before the silo is removed.

Fig. 29.99 Appearance of the bowel after being placed into a preformed silo (Medicina) whilst awake.

Fig. 29.100 Cloacal exstrophy. The gut is exposed between two hemibladders.

more complicated course. Necrotising enterocolitis is an additional potential complication.

Cloacal exstrophy

This is an uncommon condition that affects both the alimentary and urinary tracts. Typically, there is an exstrophic central segment of bowel (ileocaecal region) flanked by two hemibladders but many variations are described (Fig. 29.100). Gender assignment can be difficult and experienced multidisciplinary assessment is important. Major associated anomalies are common and reconstructive surgery is often complex (Lund and Hendren 2001).

Fig. 29.101 Incarcerated inguinal hernias. (A) This boy's right inguinal hernia was reduced by taxis and subsequently repaired. (B) This baby girl had an ovary incarcerated in her irreducible inguinal hernia and required urgent surgery.

Hernias

Inguinal

Although girls may develop an inguinal hernia, boys are affected much more frequently because of failure of closure of the processus vaginalis after testicular descent. The prevalence of inguinal hernia is greatest during infancy, when at least 1% of boys are affected. In boys, 60% of inguinal hernias occur on the right, 30% on the left and 10% are bilateral. Inguinal hernias in general and bilateral hernias in particular are much more common in premature babies, as are associated undescended testes:

- Inguinal hernias typically cause an intermittent swelling in the groin or scrotum when the baby cries or strains. If the hernia becomes obstructed (at the level of the external inguinal ring) it will manifest as a firm, tender lump in the groin or scrotum (Fig. 29.101). The baby may vomit and be irritable. Most incarcerated hernias in children can be successfully reduced by sustained gentle compression (taxis) after analgesia. Surgery is delayed for 24–48 hours to allow resolution of oedema. If reduction is impossible, emergency surgery is required because of the risk of strangulation of bowel (or ovary) and damage to the testis.
- The risk of incarceration/strangulation in an inguinal hernia is greatest in infancy and thus repair should generally be undertaken as soon as the infant is fit for surgery or prior to discharge from hospital in the case of a premature baby.

Fig. 29.102 A patent vitellointestinal duct causing an umbilical discharge. Excision of the duct was curative.

Postoperative apnoea is a potential hazard in infants less than 44 weeks' postconceptional age. Inguinal herniotomy is usually performed under general anaesthesia but regional anaesthetic techniques are valuable for some infants with respiratory problems (Peutrell and Hughes 1992). Most surgeons repair the hernia through an inguinal skin crease incision but laparoscopy has its advocates. Inguinal herniotomy is not a minor procedure in a neonate and demands anaesthetic and surgical expertise. Local complications are uncommon but may include recurrent hernia, interference with normal testicular descent and injury to the vas or vessels.

Umbilical

Incomplete regression of the vitelline duct may result in a patent vitellointestinal duct (Fig. 29.102) or a Meckel's diverticulum. An umbilical hernia is caused by incomplete closure of the umbilical ring. Most resolve spontaneously within a year or two and surgical repair is rarely necessary. Incarceration in an umbilical hernia is rare in western countries.

Developmental haemopoiesis

Introduction

The process which ensures lifelong production of all haemopoietic cells is known as haemopoiesis. Sequential changes in the regulation of haemopoiesis during development help to explain the natural history of many neonatal haematological problems. Haemopoiesis in humans begins in the yolk sac in the third week of gestation (Huyhn et al. 1995). By 5 weeks' gestation, the main site of definitive haemopoiesis is found in the aorto-gonad-mesonephros region of the dorsal aorta. Haemopoiesis in the aorta is only transient and haemopoietic stem cells migrate from there a few weeks later to the liver, which remains the main site of blood cell production throughout fetal life (Huyhn et al. 1995; Marshall and Thrasher 2001). Even though signs of haemopoiesis are also found in the bone marrow from 11 weeks' gestation, this makes only a small contribution to overall haemopoiesis until after birth (Tavian et al. 1999). Thus, for preterm infants, the liver is the main haemopoietic organ at and shortly after birth; this is likely to be a contributory factor in a number of disorders, including the haematological abnormalities seen in neonates with Down syndrome (see later sections).

Erythropoiesis in the fetus and neonate

Erythropoiesis, production of red blood cells (RBCs), has a number of distinct characteristics in term and preterm neonates compared with older children which are relevant to our understanding of neonatal anaemias:

- *Rate of haemoglobin synthesis and RBC production:* the rates of haemoglobin synthesis and of RBC production fall dramatically after birth and remain low for the first 2 weeks of life, probably in response to the sudden increase in tissue oxygenation at birth (Oski 1993). The physiological rise in RBC production begins several weeks later and by 3 months of age a healthy infant, whatever the gestation at birth, should be able to produce up to 2 ml of packed RBCs per day (Oski 1993). Studies in preterm neonates suggest that over the first 2 months of life the maximal rate of RBC production is about 1 ml/day since preterm babies receiving erythropoietin are unable to maintain their haemoglobin if >1 ml of blood per day is venesected for diagnostic purposes but can do so when sampling losses are less than this (Ohls 2002).
- *Reduced RBC lifespan:* neonatal RBCs, particularly from preterm babies, have a reduced lifespan compared with adult red cells. Calculated RBC lifespans for preterm infants are 35–50 days compared with 60–70 days for term infants and 120 days for healthy adults (Pearson 1967). The main reason for this is the many differences in the membrane of neonatal versus adult RBCs, including increased resistance to osmotic lysis, increased mechanical fragility, increased total lipid content and an altered lipid profile, increased insulin-binding sites and reduced expression of blood group antigens such as A, B and I (Oski 1993).
- *Altered RBC metabolism:* there are numerous differences in the glycolytic and pentose phosphate pathways between neonatal and adult RBCs which lead to an increased susceptibility to oxidant-induced injury (Bracci et al. 1988). In addition, neonatal RBCs have reduced levels of NADH methaemoglobin reductase (about 60% of those in adult RBCs). This makes them more likely to develop methaemoglobinaemia as they are more susceptible to the toxic effects of chemicals (e.g. nitric oxide) which oxidise

haemoglobin iron more rapidly than the maximal rate of methaemoglobin reduction; methaemoglobin levels are correspondingly slightly higher in neonates than in adults (mean 0.43 g/dl in preterm neonates, 0.22 g/dl in term neonates and 0.11 g/dl in adults) (Osaki 1993).

- *Changes in globin chain synthesis in the fetus and newborn:* the first globin chain produced is epsilon globin, followed almost immediately by α - and γ -globin chain production (Table 30.1). HbF ($\alpha_2\gamma_2$) is therefore produced from early in gestation (4–5 weeks) and is the predominant haemoglobin until after birth. Adult haemoglobin (HbA: $\alpha_2\beta_2$) remains at low levels (10–15%) until 30–32 weeks. After this, the rate of HbA production increases at the same time as HbF production falls, resulting in an average HbF level at term birth of 70–80%, HbA of 25–30%, small amounts of HbA₂ and sometimes a trace of Hb Barts (β_4) (Bard 1975). After birth, HbF falls, to ~2% at age 12 months with a corresponding increase in HbA. In term babies there is little change in HbF in the first 15 days after birth. In preterm babies who are not transfused, HbF may remain at the same level for the first 6 weeks of life before HbA production starts to increase. It is this delay in HbA production (i.e. the switch from the γ -globin of HbF to the β -globin of HbA) which can make the diagnosis of β -globin disorders difficult in the neonatal period. By contrast, the fact that α -globin chains are absolutely essential for the production of both HbF and HbA means that α -thalassaemia major causes severe anaemia from early in fetal life (Higgs 1993).
- *Erythropoietin production in the fetus and newborn:* erythropoietin is the principal cytokine regulating erythropoiesis in the fetus and newborn (Vora and Gruslin 1998; Halvorsen and Bechensteen 2002). Since erythropoietin does not cross the placenta, erythropoietin-mediated regulation of fetal erythropoiesis is predominantly under fetal control (Vora and Gruslin 1998). The liver is the main site of erythropoietin production in the fetus (Dame et al. 1998) and the only stimulus to erythropoietin production under physiological conditions is hypoxia with or without anaemia.

This explains the high erythropoietin levels in fetuses of mothers with diabetes or hypertension or those with intrauterine growth restriction (IUGR) or cyanotic congenital heart disease; erythropoietin is also increased in fetal anaemia of any cause, including haemolytic disease of the newborn (HDN) (Watts and Roberts 1999).

White cell production in the fetus and newborn

Neutrophils

There are few circulating neutrophils in first- and second-trimester blood ($0.1\text{--}0.2 \times 10^9/\text{l}$) (Campagnoli et al. 2000), after which the numbers gradually rise to reach over $2 \times 10^9/\text{l}$ by term, with slightly lower numbers in preterm neonates (Table 30.2). The principal difference between neutrophil production in the newborn and the adult is the reduced neutrophil storage pool, particularly in preterm infants and most markedly in IUGR or exposure to maternal hypertension (Koenig and Christensen 1989; Ohls et al. 1995; Christensen et al. 2000). The neutrophil storage pool reflects the available reserve of neutrophils which the fetus or neonate can mobilise in response to infection. This may contribute to the frequency of bacterial infection in preterm infants. The neutrophil storage pool is defined as the numbers of segmented neutrophils, band neutrophils and metamyelocytes in the bone marrow and so is usually inferred (by the leukocyte response to bacterial sepsis) since bone marrow examination is rarely indicated in the newborn. Various cytokines stimulate neutrophil production in vitro and in vivo (e.g. granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF)) (Ohls et al. 1995; Christensen et al. 2000).

Monocytes, eosinophils and lymphocytes

All types of leukocyte found in adult blood are also seen in the fetus and the newborn (Forestier et al. 1986); monocytes circulate from

Table 30.1 Composition of haemoglobins in the human embryo, fetus and neonate

HAEMOGLOBIN	GLOBIN CHAINS		GESTATION
	α -GLOBIN GENE CLUSTER	β -GLOBIN GENE CLUSTER*	
Embryonic			
Hb Gower-1	ζ_2	ϵ_2	From 3–4 weeks
Hb Gower-2	α_2	ϵ_2	
Hb Portland	ζ_2	γ_2	From 4 weeks
Fetal			
HbF	α_2	γ_2	From 4 weeks
Adult			
HbA	α_2	β_2	From 6–8 weeks
HbA ₂	α_2	δ_2	From 30 weeks
*The α -globin gene cluster is situated on chromosome 16 and the β -globin gene cluster on chromosome 11. Note that fetuses and neonates with α -thalassaemia major, who are unable to synthesise α -globin chains, will have Hb Portland as well as Hb Barts (β_4) detectable by haemoglobin electrophoresis or high-performance liquid chromatography.			

4–5 weeks' gestation and eosinophils from 14–16 weeks' gestation, increasing slowly to normal values at term (see Table 30.2). There are few studies of lymphopoiesis in the human fetus; both T lymphocytes and B lymphocytes are found in low numbers in fetal liver at 7 and 8 weeks' gestation, respectively (Hann 1991), and T lymphocytes are detectable in fetal blood, marrow and thymus during the second trimester (Pahal et al. 2000). By term, T lymphocytes form 40–45% of circulating mononuclear cells, with a CD4:CD8 ratio of around 5:1, slightly higher than in adult blood (3.1:1). B lymphocytes are found in fetal blood and bone marrow from 12 weeks' gestation and constitute 4–5% of circulating mononuclear cells by term (Hann 1991).

Table 30.2 Representative normal haematological values at birth and over the first 2 months of life in term babies*

	BIRTH	2 WEEKS	2 MONTHS
Hb (g/dl)	14.9–23.7	13.4–19.8	9.4–13
Haematocrit	0.47–75	0.41–0.65	0.28–0.42
MCV (fl)	100–125	88–110	77–98
Reticulocytes ($\times 10^9/l$)	110–450	10–85	35–200
WBCs ($\times 10^9/l$)	10–26	6–21	5–15
Neutrophils ($\times 10^9/l$)	2.7–14.4	1.5–5.4	0.7–4.8
Monocytes ($\times 10^9/l$)	0–1.9	0.1–1.7	0.4–1.2
Lymphocytes ($\times 10^9/l$)	2.0–7.3	2.8–9.1	3.3–10.3
Eosinophils ($\times 10^9/l$)	0–0.85	0–0.85	0.05–0.9
Basophils ($\times 10^9/l$)	0–0.1	0–0.1	0.02–0.13
Nucleated RBCs ($\times 10^9/l$)	<5	<0.1	<0.1
Platelets ($\times 10^9/l$)	150–450	150–450	150–450

*These data are obtained from a number of sources and have been chosen to represent data most useful for interpreting the significance of haematological results.
Hb, haemoglobin; MCV, mean corpuscular volume; WBC, white blood cells; RBC, red blood cells.

Megakaryocytopoiesis and platelet production in the fetus and newborn

Platelets appear in the circulation at 5–6 weeks' gestation (Hann 1991). During the second trimester, the platelet count rises to normal adult values ($175\text{--}250 \times 10^9/l$) (Forestier et al. 1986). Thus, a platelet count of less than $150 \times 10^9/l$ is abnormal even in the most preterm neonate. The principal cytokine regulating platelet production in the fetus and newborn is thrombopoietin, as in adults (Watts et al. 1999). There are several differences between megakaryocytopoiesis and its regulation in the fetus and newborn compared with adults which may contribute to the frequent occurrence of thrombocytopenia in sick neonates. Fetal megakaryocytes are smaller and more immature (Hegyi et al. 1991; de Alarcon and Graeve 1996); the numbers of megakaryocyte progenitor cells, the precursor cells for maintaining megakaryocyte and platelet production, are reduced; and the ability to produce thrombopoietin is reduced, limiting the capacity to upregulate platelet production at times of increased demand, e.g. during thrombocytopenia in neonatal sepsis (Watts et al. 1999; Albert et al. 2000).

Neonatal anaemia and other red cell disorders

Introduction and definition

Anaemia is the commonest haematological abnormality in the newborn. In the majority of neonates, the causes are straightforward, since they reflect a combination of well-recognised physiological changes and iatrogenic blood letting. However, it is important to identify those neonates with pathological anaemia who require additional investigations and more tailored management. In the neonatal period, the most frequent diseases associated with anaemia are immune haemolysis and genetic red cell disorders. A logical approach and appropriate use of straightforward investigations, as outlined below, reveal the cause in most babies. Treatment options for neonatal anaemia are limited and are based mainly on sensible use of blood transfusion (see pp. 780–782) and prevention of anaemia.

Normal values for red blood cells and blood volume

Normal values at birth for haemoglobin, haematocrit and mean corpuscular volume (MCV) for term and preterm babies are shown in Table 30.2 and Table 30.3, respectively, and in Appendix 1.

Table 30.3 Representative normal haematological values at birth in preterm babies

	24–25 WEEKS	26–27 WEEKS	28–29 WEEKS	30–31 WEEKS
Hb (g/dl)	19.4 ± 1.5	19.0 ± 2.5	19.3 ± 1.8	19.1 ± 2.1
Haematocrit	0.63 ± 0.04	0.62 ± 0.08	0.60 ± 0.07	0.60 ± 0.08
MCV (fl)	135 ± 0.02	132 ± 14.4	131 ± 13.5	127 ± 12.7
Reticulocytes ($\times 10^9/l$)	279 ± 23	454 ± 15	347 ± 12	278 ± 10
Platelets ($\times 10^9/l$)	150–450	150–450	150–450	150–450

Hb, haemoglobin; MCV, mean corpuscular volume.
Adapted from Oski (1993).

In term babies, the haemoglobin, haematocrit and red cell indices fall slowly over the first few weeks, reaching a mean haemoglobin of 13–14 g/dl at 4 weeks of age and 9.5–11 g/dl at 7–9 weeks of age, with a lower limit of normal for the MCV and mean corpuscular haemoglobin (MCH) of 77 fl and 26 pg, respectively. For preterm infants, these changes may be difficult to interpret, because of their variable clinical course and transfusion requirements. However, studies of well preterm infants carried out in the 1970s show a more rapid and steeper fall in haemoglobin, reaching a mean of 6.5–9 g/dl at 4–8 weeks' postnatal age (Oski 1993). The reticulocyte count falls rapidly after birth as erythropoiesis is suppressed, and starts to increase in term babies at 7–8 weeks of age to reach 35–200 $\times 10^9/l$ (1–1.8%) at 2 months of age, and in preterm babies at 6–8 weeks of age (Matoth et al. 1971; Brown et al. 1983; Oski 1993). Normal blood volume at birth varies with gestational age and the timing of clamping of the cord (Linderkamp et al. 1992). In term infants, the average blood volume is 80 ml/kg (range 50–100 ml/kg), and in preterm infants is higher at 106 ml/kg (range 85–143 ml/kg) (Sisson et al. 1959; Usher and Lind 1965). Term and preterm babies have adequate stores of iron, folic acid and vitamin B₁₂ at birth. However, stores of both iron and folic acid are lower in preterm infants and are depleted more quickly, leading to deficiency after 2–4 months if the recommended daily intakes are not maintained (see Ch. 16, part 3). In general, even term neonates with a normal haemoglobin at birth will have depleted their iron stores by the time they have doubled their birthweight (Rao and Georgieff 2002).

There are no useful published normal ranges for the numbers of circulating nucleated red cells. Nevertheless, a useful 'rule of thumb' is that values of less than 5 nucleated RBCs per 100 white cells in a term baby and <20 nucleated RBCs per 100 white blood cells in a preterm baby can be considered normal for the first 1–2 days of life. The commonest causes of increased numbers of circulating nucleated RBCs are:

- haemolysis (common in rhesus haemolytic disease and α -thalassaemia major but uncommon in other types of haemolysis)
- haemorrhage (especially fetomaternal haemorrhage)
- chronic tissue hypoxia in utero (IUGR, maternal hypertension, maternal diabetes)
- perinatal asphyxia.

Definition of anaemia

Anaemia can be defined as a haemoglobin concentration below the normal range for a population of age- and sex-matched individuals. Normal values for term and preterm infants at birth are shown in Tables 30.2 and 30.3; from this it can be seen that, regardless of gestation, any neonate with a haemoglobin of <14 g/dl at birth in a properly taken blood sample should be considered anaemic. Not every neonate with a haemoglobin concentration at birth of <14 g/dl needs detailed further investigation, but thought should be given to the cause (Table 30.4) and appropriate investigations instituted. Where the reduced haemoglobin does not fit the clinical picture, the first step should be to repeat the sample, since in many cases the measured haemoglobin concentration is inaccurate because of the site of sampling (heelprick versus venous blood) or the way in which the sample was collected. The haemoglobin concentration in venous samples is lower than in heelprick samples collected simultaneously: in the first few hours of life this difference averages 2–4 g/dl and is greater at lower gestational ages (Thurlbeck and McIntosh 1987; Oski 1993). The difference between the venous and capillary haemoglobin falls with increasing gestational age, and also with increasing postnatal age, such that by the fifth day of life

Table 30.4 Causes of neonatal anaemia

Impaired red cell production

Diamond–Blackfan anaemia
Congenital infection, e.g. cytomegalovirus, rubella
Congenital dyserythropoietic anaemia
Pearson syndrome
Congenital leukaemia

Increased red cell destruction (haemolysis)

Alloimmune: haemolytic disease of the newborn (Rh, ABO, Kell, other)
Autoimmune, e.g. maternal autoimmune haemolysis
Red cell membrane disorders, e.g. hereditary spherocytosis
Red cell enzyme deficiencies, e.g. pyruvate kinase deficiency
Some haemoglobinopathies, e.g. α -thalassaemia major, HbH disease
Infection, e.g. bacterial, syphilis, malaria, cytomegalovirus, *Toxoplasma*, herpes simplex
Macro/microangiopathy, e.g. cavernous haemangioma, disseminated intravascular coagulation
Galactosaemia

Blood loss

Occult haemorrhage before or around birth, e.g. twin-to-twin, fetomaternal, ruptured vasa praevia
Internal haemorrhage, e.g. intracranial, subaponeurotic, intraperitoneal
Iatrogenic: due to frequent blood sampling

Anaemia of prematurity

Impaired red cell production plus reduced red cell lifespan

there is almost no difference in haemoglobin concentration between a well-taken heelprick sample and a venous sample (Oski 1993).

The influence of cord clamping

The other major influence on haemoglobin concentration at birth is the timing of cord clamping and the position of the baby at the time of clamping. In term babies, the placental vessels contain around 100 ml of blood at birth. It has been estimated that 25% of the placental blood is transfused within the first 15 seconds and 50% (i.e. 50 ml in a term baby) by the end of the first minute (Linderkamp et al. 1992). The difference in haemoglobin concentration in the baby between early and late cord clamping is around 3 g/dl (Yao et al. 1969). Babies held below the level of the placenta continue to gain blood until the cord is clamped and have higher haemoglobin levels than those held above the level of the placenta, who may lose blood into the placenta until the cord is clamped (Yao et al. 1969).

Physiological impact of anaemia in the neonate

The clinical significance of anaemia in the newborn depends on whether or not the baby is able to maintain adequate tissue oxygenation. This does not depend solely upon the haemoglobin concentration since tissue oxygenation is also influenced by cardio-pulmonary function and by the ability of the haemoglobin to

unload the oxygen it is carrying. Fortunately, the oxygen-unloading capacity of blood increases progressively from birth, reflecting the position of the haemoglobin–oxygen dissociation curve.

In neonates, the two most important factors determining the position of the haemoglobin–oxygen dissociation curve are the concentrations of HbF and of 2,3-diphosphoglycerate (2,3-DPG) within the RBCs: high HbF and low 2,3-DPG both cause the curve to shift to the left, i.e. the affinity of haemoglobin for oxygen is increased, so less oxygen is released to the tissues. This is the situation just after birth in both term and preterm babies, as both have HbF concentrations above 50% at birth. The high oxygen affinity may be more of a problem for preterm babies since the HbF levels are >90% in babies of 24–28 weeks' gestation, although this may not be significant in practice since very preterm neonates are more likely to require transfusion over the first few weeks of life. Over the first few months of life, 2,3-DPG levels rise and HbF levels fall, so the haemoglobin–oxygen dissociation curve gradually shifts to the right, i.e. the oxygen affinity of haemoglobin falls and oxygen delivery to the tissues increases, to some extent ameliorating the effects of the falling haemoglobin over the first months of life.

Pathogenesis and causes of neonatal anaemia

Anaemia in the neonatal period has distinct physiological features compared with older children and a distinct pathogenesis. Interpretation of diagnostic investigations has to be made on a background of the developmental changes affecting the red cell membrane, red cell enzyme concentrations and the types and rate of haemoglobin production, which vary with gestational and postnatal age. Diagnostic tests are also often affected by whether the baby has been transfused. Furthermore, anaemia in the neonate may be due to pregnancy-related or pre-existing disorders in the mother, such as the presence of red cell alloantibodies or genetic disorders. It is therefore important to remember that in many cases evaluating the blood count and blood film of the parents is the quickest way of identifying the underlying diagnosis in the neonate.

The principal causes of neonatal anaemia are shown in Table 30.4. In general, anaemia can result from one or more of the following mechanisms:

- inappropriately reduced red cell production
- increased red cell destruction/reduced red cell lifespan
- blood loss
- a combination of these mechanisms (anaemia of prematurity).

Neonatal anaemia due to reduced red cell production

Anaemia due to reduced red cell production is not common in the neonatal period. Nevertheless, it is clinically important, because several of the disorders that present in this way are associated with severe, lifelong problems. The main diagnostic clues to reduced red cell production are the combination of a low reticulocyte count ($<20 \times 10^9/l$) together with a negative direct antiglobulin test (DAT; Coombs' test). The other useful diagnostic point is whether the disorder is confined to the red cell series (i.e. anaemia in the presence of a normal white cell and platelet count) or whether the blood count suggests that the white cells and/or platelets are also involved.

The most important causes are congenital infections (particularly due to parvovirus) and genetic disorders. Where failure of blood cell production is confined to the red cell series, as with

Diamond–Blackfan anaemia (DBA) and most episodes of parvovirus infection, the anaemia is said to be due to red cell aplasia. Reduced red cell production may also be part of a general failure of haemopoiesis and accompanied by leukopenia and/or thrombocytopenia, as seen in congenital infection due to cytomegalovirus (CMV), in congenital leukaemias (see p. 770 and Ch. 36) and in congenital bone marrow failure syndromes such as Pearson syndrome (see p. 761).

Anaemia and congenital infection

Infections which cause anaemia due to reduced red cell production include parvovirus B19, CMV, toxoplasmosis, congenital syphilis, rubella and herpes simplex (Brown and Abernathy 1998; Brown 2000). Identification of the causative organism is usually based on clinical suspicion prompted by well-recognised associated findings such as chorioretinitis, jaundice, pneumonitis, skin lesions, IUGR and hepatosplenomegaly, followed by specific diagnostic microbiological investigations. In infection due to CMV, toxoplasma or herpes simplex, the anaemia and reticulocytopenia are usually relatively mild (Brown and Abernathy 1998). In addition, the blood film often shows abnormal 'viral' lymphocytes, thrombocytopenia and/or neutropenia. Congenital parvovirus B19 can cause particular diagnostic difficulties and is discussed below (Brown 2000).

Parvovirus B19 and fetal/neonatal anaemia

Maternal infection with parvovirus B19 causes fetal anaemia which is severe enough to lead to intrauterine death in 9% of cases (Public Health Laboratory Service Working Party on Fifth Disease 1990; Miller et al. 1998; Brown 2000). A diagnosis of fetal parvovirus B19 should be considered in every 'unexplained' case of fetal hydrops (Table 30.5) since it has been estimated that parvovirus B19 is responsible for 15% of cases of non-immune hydrops (Yaegashi et al. 1994; Jordan 1996; Lallemand et al. 1999). In addition to anaemia, parvovirus infection causes marked reticulocytopenia (usually $<10 \times 10^9/l$) and thrombocytopenia may also occur. The diagnosis of parvovirus B19 infection is primarily based on maternal serology together with the demonstration of B19 DNA in the fetus/neonate by dot blot hybridisation or polymerase chain reaction (PCR) (Brown 2000; Heegaard and Brown 2002). Where results are negative on blood samples but clinical suspicion of parvovirus is high, PCR for B19 should also be carried out on bone marrow (Brown et al. 1983). Management depends on the severity

Table 30.5 Haematological causes of hydrops fetalis (see Ch. 31 for other causes)

Reduced red cell production

Parvovirus B19
Diamond–Blackfan anaemia
Congenital dyserythropoietic anaemia
Congenital leukaemia

Increased red cell destruction (haemolysis)

Pyruvate kinase deficiency
 α -thalassaemia major (or HbH hydrops)
Haemolytic disease of the newborn – rhesus, Kell, ABO (rare)

Blood loss

Twin-to-twin transfusion
Fetomaternal haemorrhage

of the anaemia – severe cases diagnosed in utero may be treated by intrauterine transfusion; for those that survive, the majority have no long-term sequelae. However, a small number of neonates with chronic red cell aplasia, with or without evidence of persistent B19 DNA by PCR, have been reported, and for such cases intravenous immunoglobulin (IVIG) should be given to try and eradicate persistent viral infection (Brown 2000; Fisch et al. 2000).

Failure of red cell production due to genetic disorders

Congenital or inherited disorders that usually or not infrequently present with neonatal anaemia due to reduced red cell production include DBA, congenital dyserythropoietic anaemia (CDA) and Pearson syndrome. The other inherited bone marrow failure syndromes, such as Fanconi's anaemia, rarely present at birth.

Diamond–Blackfan anaemia

The principal cause of congenital red cell aplasia is DBA (Fisch et al. 2000), which has an incidence of 5–7 cases per million live births. There is a clear family history in 20% of cases (both autosomal dominant and autosomal recessive inheritance are reported); the remaining 80% are sporadic. Affected children nearly always present in the first year of life; most diagnoses are made around 2–3 months of age, but 25% of cases present at birth and rare cases present as mid-trimester fetal anaemia and hydrops (Ball et al. 1996; Vlachos et al. 2008). The usual presentation is with anaemia in an otherwise healthy baby; 40% of infants have associated congenital anomalies, particularly craniofacial dysmorphism, IUGR, neck anomalies (Klippel–Feil syndrome) and thumb malformations (e.g. triphalangal or bifid thumbs) (Ball et al. 1996; Vlachos et al. 2008) similar to those seen in Fanconi's anaemia. The important laboratory features are normochromic anaemia (which may be macrocytic), reticulocytopenia and absent erythroid precursors on the bone marrow aspirate. It is important to exclude parvovirus infection by appropriate serology and dot blot testing, and Fanconi's anaemia by diepoxybutane stress testing of peripheral blood lymphocytes (Giampietro et al. 1993). If these tests are negative, the only other differential diagnosis of red cell aplasia with absent red cell precursors is transient erythroblastopenia of childhood, which, in contrast to DBA, resolves within a couple of months. Although bone marrow examination is required to diagnose DBA, other useful tests include red cell adenosine deaminase levels, which are elevated in most affected patients and sometimes in parents (Vlachos et al. 2008) and genetic analysis for mutations in ribosomal protein genes, which are present in ~50% of families and can be investigated in specialised laboratories (Lipton and Ellis 2010). In the neonatal period, the treatment of DBA is red cell transfusion. Up to 75% of children with DBA respond to steroids and can often be weaned off transfusions, but this approach is not usually tried until after the first year of life (Vichinsky et al. 1988). DBA is a rather unpredictable disease: some cases resolve spontaneously; others wax and wane; but more than half of affected children have lifelong transfusion or steroid dependence and may be treated by bone marrow transplantation (Vlachos et al. 2008; Lipton and Ellis 2010).

Congenital dyserythropoietic anaemia

The CDAs are a rare group of disorders characterised by failure of red cell production due to ineffective erythropoiesis. Most cases are autosomal recessive and a history of parental consanguinity is not uncommon. In contrast to DBA, the bone marrow has vastly increased numbers of erythroid precursors but they are grossly abnormal and do not properly differentiate into mature RBCs. CDA

usually presents during childhood. However, a number of neonates with CDA presenting at birth or during fetal life have been reported and in severe cases the presentation may be with hydrops fetalis (Remacha et al. 2002). Most affected babies are normally grown with no dysmorphic features, have a normocytic anaemia with normal white cells and platelets but a low reticulocyte count and transfusion-dependent anaemia. CDA type I is due to mutations in the codanin-1 gene (Dgany et al. 2002) and CDA type II, which is the most common type of CDA, has recently been shown to be due to mutations in the *SEC23B* gene (Schwarz et al. 2009). The prognosis of CDA is extremely variable. For transfusion-independent children with CDA, lifespan is usually normal and quality of life is good. For transfusion-dependent children, the treatment options are:

- splenectomy, which renders a small proportion of children transfusion-independent with a normal lifespan
- bone marrow transplantation, the only curative treatment, but one which carries a 10% risk of mortality or graft rejection
- lifelong red cell transfusion with iron chelation therapy, which carries a similar prognosis to children with β -thalassaemia major (i.e. median survival now >50 years with good treatment compliance).

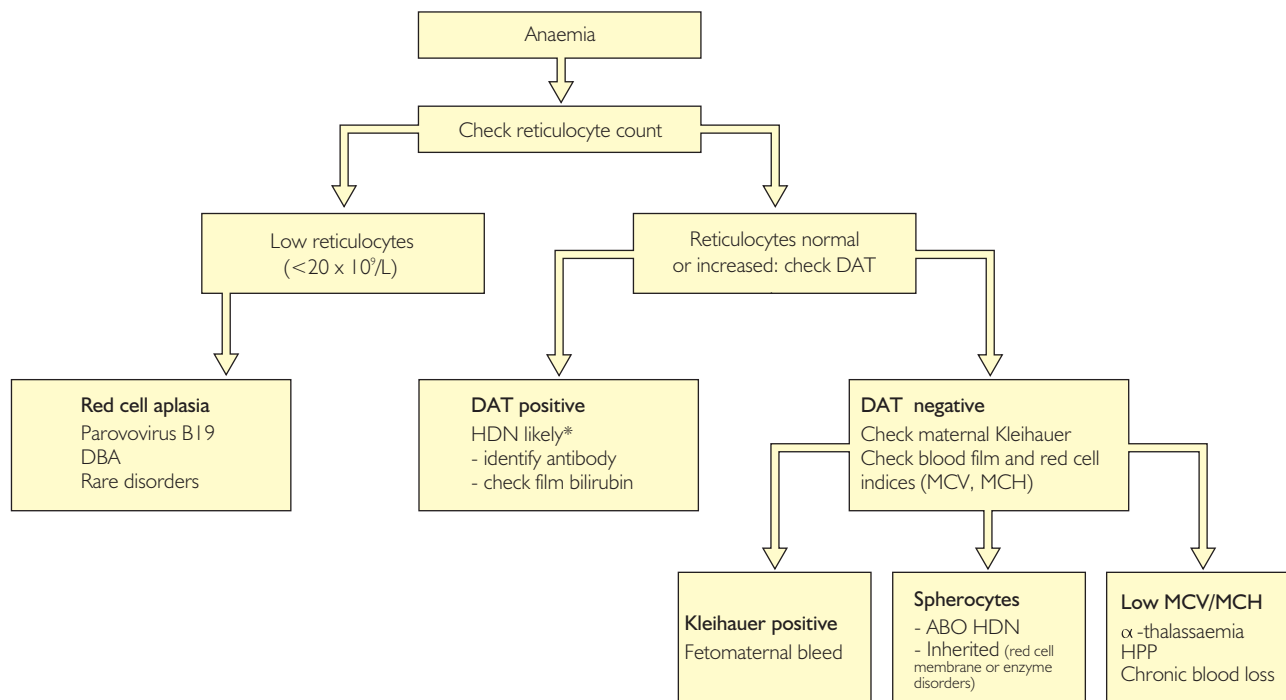

Pearson syndrome

This rare disease is caused by mutations in mitochondrial DNA (Smith et al. 1995). It often presents in neonates who are small-for-gestational-age and thrive poorly in the first few weeks of life (Smith et al. 1995). The anaemia is normocytic and associated thrombocytopenia and neutropenia are common; abnormal leukocyte vacuolation may be seen in the peripheral blood and highly characteristic vacuolation of early erythroid cells on the marrow aspirate should prompt blood to be sent for mitochondrial DNA analysis to establish the diagnosis. The prognosis of Pearson syndrome is very poor: few children survive beyond the second year of life.

Anaemia due to increased red cell destruction (haemolytic anaemia)

After anaemia of prematurity and anaemia due to blood letting, haemolysis is the commonest cause of neonatal anaemia. Haemolysis should always be investigated even if the anaemia is mild and apparently trivial. This is because transient or mild haemolysis in the neonatal period may be the clue to an underlying problem with more serious manifestations later on in childhood (e.g. red cell enzymopathies) or to problems which might affect future siblings (e.g. alloimmune anaemia due to maternal red cell antibodies).

The principal clues which suggest a haemolytic anaemia are: increased numbers of reticulocytes and/or circulating nucleated RBCs, unconjugated hyperbilirubinaemia, a positive DAT (if immune) and characteristic changes in the morphology of the red cells on a blood film (e.g. hereditary spherocytosis). The main types of neonatal haemolytic anaemia are listed in Table 30.4 and a useful algorithm to guide investigations is shown in Figure 30.1. It is usually straightforward to distinguish the cause, although rarer causes require specialist investigations which should be discussed with a haematologist once the basic investigations are to hand. The first step should be a DAT, which will be positive only in the presence of immune haemolytic anaemia and not in non-immune haemolysis. The main cause of immune haemolytic anaemia is HDN (see below). The main causes of non-immune haemolysis in neonates are:

*Administration of prophylactic antenatal anti-D to Rhesus D-negative mothers may cause a weakly positive DAT in the baby at birth. Provided there is a clear history of antenatal prophylaxis and the FBC and blood film are normal, it is not necessary to arrange further investigation and follow up of such babies.

Fig. 30.1 A diagnostic algorithm for neonatal anaemia. The most useful screening tests for investigating unexplained neonatal anaemia are the reticulocyte count, the direct antiglobulin test and the mean cell volume (MCV) of the red blood cells. DAT, direct antiglobulin test (Coombs' test); DBA, Diamond–Blackfan anaemia; G6PD, glucose-6-phosphate dehydrogenase; HDN, haemolytic disease of the newborn; HS, hereditary spherocytosis; MCH, mean cell haemoglobin; HPP, hereditary pyropoikilocytosis; FBC, full blood count.

- red cell membrane disorders
- red cell enzymopathies
- haemoglobinopathies.

A number of congenital and primary infections can also cause haemolytic anaemia in the neonatal period, including CMV, toxoplasmosis, congenital syphilis, rubella, herpes simplex and, rarely, malaria.

Immune haemolytic anaemias, including haemolytic disease of the newborn

By far the most common cause of DAT-positive haemolysis is HDN due to transplacental passage of maternal IgG alloantibodies to red cell antigens. Although modern DAT reagents are very sensitive, a negative DAT is sometimes found in ABO HDN due to anti-A or anti-B (Herschel et al. 2002). Maternal autoimmune haemolytic anaemia very occasionally causes a positive DAT in the neonate; however, both haemolysis and anaemia in the baby are extremely rare.

The principal alloantibodies that cause significant anaemia due to HDN are those against rhesus antigens (anti-D, anti-c and anti-E), anti-Kell, anti-Kidd (J^k), anti-Duffy (F^y) and antibodies of the MNS blood group system, including anti-U. Anti-D remains the most frequent alloantibody to cause significant haemolytic anaemia, affecting 1 in 1200 pregnancies (Howard et al. 1998; Thompson 2002). Anti-Kell antibodies are less common but can cause severe

fetal and neonatal anaemia since they inhibit erythropoiesis as well as causing haemolysis (Vaughan et al. 1998). Most babies with HDN present with jaundice and/or anaemia and are born to women with known antibodies. In neonates with severe anaemia, there is often evidence of extramedullary haemopoiesis, including hepatosplenomegaly and occasionally skin lesions producing the clinical appearance of 'blueberry muffin baby' (Bowden et al. 1989; Waldron and de Alarcon 1999).

HDN due to ABO antibodies

ABO haemolytic disease occurs only in offspring of women of blood group O and is confined to the 1% of such women who have high-titre IgG antibodies. Haemolysis due to anti-A is more common (1 in 150 births) than anti-B. In contrast to anti-Rhesus antibodies, both anti-A and anti-B usually cause hyperbilirubinaemia without significant neonatal anaemia. This is mainly because there are relatively few group A or B antigen sites on neonatal red cells, allowing the antibody-coated cells to persist for longer in the circulation (Osaki 1993). As a reflection of this, the blood film in ABO haemolytic disease characteristically shows very large numbers of spherocytes with little or no increase in nucleated red cells; this contrasts to rhesus HDN, where there are few spherocytes and vast numbers of circulating nucleated red cells. The DAT in ABO HDN may be negative. Management of ABO HDN usually just requires phototherapy; however, close monitoring is essential and exchange transfusion is occasionally required, particularly in cases of ABO HDN

due to anti-B antibodies, which may cause severe anaemia as well as hyperbilirubinaemia (Waldron and de Alarcon 1999). Hydrops has occasionally been described.

Management of HDN

The antenatal diagnosis and management of pregnancies affected by red cell alloimmunisation require cooperation between obstetric, paediatric and haematology teams (Grant et al. 2000). All neonates at risk should have cord blood taken for measurement of haemoglobin, bilirubin and a DAT and should remain in hospital until hyperbilirubinaemia and/or anaemia have been properly managed. Phototherapy should be given from birth to all rhesus-alloimmunised infants with haemolysis, as the bilirubin can rise steeply after birth and this expectant approach will prevent the need for exchange transfusion in some infants. In HDN due to anti-Kell, anaemia is usually more prominent than jaundice and minimal phototherapy may be necessary despite severe anaemia (Grant et al. 2000). Systematic reviews have found that treatment of neonates with alloimmune haemolysis with IVIG does reduce the need for exchange transfusion (Alcock and Liley 2002; Gottstein and Cooke 2003). Current National Institute for Health and Clinical Excellence guidance (neonatal jaundice) is to use IVIG when the serum bilirubin continues to rise at more than 8.5 $\mu\text{mol/l/h}$ in spite of phototherapy, although further research is recommended.

Exchange transfusion in HDN is required for:

- severe anaemia: haemoglobin <10 g/dl at birth (with the possible exception of anti-Kell, as mentioned above)
- severe or rapidly increasing hyperbilirubinaemia
- signs of bilirubin encephalopathy.

Details of the product to use for exchange transfusion are given on p. 782 and are summarised in the current *British Committee for Standards in Haematology (BCSH) guidelines* (2004).

'Late' anaemia presents at a few weeks of age in some babies with milder haemolytic disease who do not require exchange transfusion and in babies who have had earlier exchange transfusion. The blood film shows evidence of ongoing haemolysis and the anaemia is aggravated by the normal postnatal suppression of erythropoiesis. Such babies may require 'top-up' transfusion for symptomatic anaemia; conventional guidelines for neonatal transfusion can be followed (see Table 30.13) but irradiated blood must be used for infants previously receiving intrauterine transfusion, to prevent the risk of transfusion-associated graft-versus-host disease (TA-GVHD) (*British Committee for Standards in Haematology, Transfusion Task Force* 2004). Thus, all babies found to have a strongly positive DAT at birth and all treated by intrauterine transfusion must be followed up to monitor the rate of haemoglobin fall. It is important to note that administration of prophylactic antenatal anti-D to rhesus D-negative mothers quite commonly causes a weakly positive DAT in the baby at birth. Provided there is a clear history of antenatal prophylaxis and the Hb and the blood film are normal, it is not necessary to arrange further investigation and follow-up of such babies. It is worth noting that babies with ABO HDN rarely require 'top-up' transfusion unless severe anaemia in the first few days of life (Hb <10 g/dl) has been a feature. Where the haemoglobin is falling more rapidly than normal, particularly in babies with unconjugated hyperbilirubinaemia, monitoring must be continued until the jaundice resolves and the haemoglobin reaches a plateau. This may take 8 weeks and it may be helpful to ask the haematologist to review the blood films each time, to look for evidence of ongoing haemolysis. Folic acid (500 $\mu\text{g/kg/day}$) should be given to all babies with haemolytic anaemia until 3 months of age; folic acid is not necessary for babies with ABO HDN who are not anaemic. Erythropoietin has been used to prevent the need for 'top-up' transfusion

for late anaemia; both failures and successes of this approach have been reported and erythropoietin is unlikely to prevent the need for transfusion where ongoing haemolysis is brisk (Zuppa et al. 1999; Pessler and Hart 2002).

Neonatal haemolytic anaemia due to red cell membrane disorders

A number of red cell membrane disorders may present in the neonatal period. The three most common types of presentation are:

1. unexplained haemolysis with jaundice but usually only moderate anaemia (usually due to hereditary spherocytosis)
2. as an incidental finding on a routine blood film in the absence of unusual jaundice or anaemia (usually hereditary elliptocytosis)
3. severe, transfusion-dependent haemolytic anaemia with a characteristic very low MCV of 50–60 fl (usually due to hereditary pyropoikilocytosis (HPP)).

The main clues that a neonate has a red cell membrane disorder are a family history, otherwise unexplained haemolysis and an abnormal blood film. Red cell membrane disorders can nearly always be recognised by the characteristic shape of red cells on a blood film. However, the identification of the exact type of membrane abnormality is more complex and requires specialised investigations on both the neonate and the parents and close liaison with a haematologist. The osmotic fragility test has largely been replaced by the dye-binding test which is carried out on a small sample of peripheral blood but may need to be performed in a specialised centre (Tse and Lux 1999; King et al. 2008). It is important to carry out these definitive diagnostic investigations (red cell membrane studies) on pretransfusion blood samples to minimise diagnostic confusion due to transfused cells and to check the blood count and film of both parents if possible (Palek and Jarolim 1993).

A brief summary of the three main clinical disorders presenting in neonates is given below; for more detailed information, the reader is referred to comprehensive reviews (Tse and Lux 1999; Delaunay 2002; Bolton-Maggs et al. 2004).

Hereditary spherocytosis

This is the commonest red cell membrane defect. It occurs in 1 in 5000 live births to parents of northern European extraction, but is less frequently seen in other ethnic groups (Delaunay 2002). It is autosomal dominant, but around 25% of cases are sporadic due to new mutations. Hereditary spherocytosis is genetically heterogeneous – mutations in spectrin, ankyrin, protein 4.1 and protein 3 have all been reported (Delaunay 2002). The usual presentation of hereditary spherocytosis in the neonate is with unconjugated hyperbilirubinaemia. Most affected neonates are not anaemic, but a small proportion have anaemia severe enough to require transfusion. The blood film in hereditary spherocytosis shows moderate numbers of spherocytes; the appearance is identical to that of ABO haemolytic disease, but the two disorders are distinguishable by the negative DAT in hereditary spherocytosis. While some babies will require one or two transfusions during the first 1–2 months of life, very few remain transfusion-dependent after this time and it is important to stop transfusions to evaluate the nadir haemoglobin reached. All children with hereditary spherocytosis should also receive folic acid supplementation (from 500 $\mu\text{g/kg/day}$ in the first 6 months of life and a total daily dose of 2.5 mg from 6 months until 10 years of life, increasing to 5 mg daily thereafter). Splenectomy almost invariably induces complete remission of haemolytic anaemia (and therefore the need for folic acid prophylaxis) but is only indicated for

more severely affected children and virtually always deferred until after the age of 6 years.

Hereditary elliptocytosis

This is a more complex disorder. It is caused by different mutations in the genes for spectrin, ankyrin or protein 4.1 (Tse and Lux 1999; Delaunay 2002). In the common, autosomal dominant form of hereditary elliptocytosis, the heterozygotes have no clinical manifestations (i.e. no anaemia and no jaundice) apart from elliptocytes on the blood film. No treatment is required and folic acid prophylaxis is unnecessary, as folate deficiency is not a feature of this condition. Neonates who are homozygous or compound heterozygotes for hereditary elliptocytosis mutations have severe haemolytic anaemia; the most common form is HPP.

Hereditary pyropoikilocytosis

Neonates with HPP have more than one mutation in a red cell membrane protein (they may be homozygous or compound heterozygotes) (Tse and Lux 1999; Delaunay 2002). HPP is uncommon but is important because it causes severe, transfusion-dependent haemolytic anaemia which does not improve with age. The diagnosis of HPP should easily be made by examining blood films from the baby (which shows lots of bizarre fragmented red cells and microspherocytes) and both parents (one or both often have red cell elliptocytosis); a useful diagnostic clue is the low MCV at birth (<60 fl). Red cell transfusion is usually necessary until the child is old enough to undergo splenectomy, to which there is an excellent response.

Neonatal haemolysis due to red cell enzymopathies

The principal red cell enzymopathies which present in the neonatal period are glucose-6-phosphate dehydrogenase (G6PD) deficiency and pyruvate kinase (PK) deficiency. They usually present with unconjugated hyperbilirubinaemia; clinically, they are indistinguishable from red cell membrane disorders, although anaemia is uncommon in neonates with G6PD deficiency. Unlike with the membrane disorders, there are often no diagnostic changes on the blood film.

Glucose-6-phosphate dehydrogenase deficiency

G6PD deficiency is seen in all ethnic groups but has a high prevalence in individuals from central Africa (20%) and the Mediterranean (10%). The G6PD gene is on the X chromosome and therefore most affected neonates are boys, although female carriers may sometimes be identified as a result of neonatal jaundice screens. In neonatal G6PD deficiency, jaundice usually presents within the first few days of life and is often severe; anaemia is extremely rare and the blood film is completely normal, thus the diagnosis must be made by assaying G6PD on a peripheral blood sample (Luzzatto 1993). It is not clear why some, but not all, G6PD-deficient neonates develop neonatal jaundice. In addition, the pathogenesis of the jaundice is also unclear, since most babies with G6PD deficiency have no evidence of haemolysis. The most important management issues in neonatal G6PD deficiency are close monitoring of the bilirubin, particularly where interactions with other risk factors for neonatal hyperbilirubinaemia are present, such as Gilbert syndrome or hereditary spherocytosis, since kernicterus has been reported in this setting (Kaplan 2001; Kaplan and Hammerman 2002), and counselling parents of affected babies about which medicines, chemicals and foods may precipitate haemolysis (Table 30.6). If exchange transfusion is required for severe hyperbilirubinaemia, conventional guidelines for exchange transfusion can be

Table 30.6 Drugs and chemicals associated with haemolysis in patients who are glucose-6-phosphate dehydrogenase (G6PD)-deficient

Antimalarials

Primaquine
Pamaquine
(Quinine)*
(Chloroquine)*

Antibiotics

Nitrofurantoin
Sulphonamides, e.g. dapsone
Sulphonamides,[†] e.g. sulphamethoxazole (Septrin)
Quinolones, e.g. nalidixic acid, ciprofloxacin
(Chloramphenicol)[‡]

Analgesics

Aspirin (in high doses)
Phenacetin

*Acceptable in acute malaria.

[†]Some sulphonamides do not cause haemolysis in most G6PD-deficient patients, e.g. sulfadiazine.

[‡]To be avoided in some types of G6PD deficiency (can be taken by patients with the common, African A-form of G6PD deficiency).

followed (see Chs 29.2 and 44). Certain uncommon variants of G6PD deficiency are associated with chronic haemolysis, and for these children folic acid supplements should be given (Luzzatto 1993). However, for the vast majority of patients there is no chronic haemolysis and no anaemia and therefore folic acid supplements are not indicated.

Pyruvate kinase deficiency

PK deficiency is the second most common red cell enzymopathy in neonates. It is autosomal recessive and clinically heterogeneous, varying from anaemia severe enough to cause hydrops fetalis to a mild unconjugated hyperbilirubinaemia (Gilsanz et al. 1993; Zanella and Bianchi 2000). In severe cases, the jaundice has a rapid onset within 24 hours of birth and exchange transfusion may be required (Gilsanz et al. 1993). The diagnosis is made by measuring pretransfusion red cell PK activity; in mild cases, the PK activity may be relatively modestly reduced, making the diagnosis difficult, and it is often useful to assay levels in the parents for confirmation. The blood film is sometimes distinctive but more often shows non-specific changes of non-spherocytic haemolysis and therefore it is good practice to assay PK in all babies with unexplained haemolysis after the common causes have been excluded. Management in the neonatal period depends on the severity of the jaundice and anaemia; some, but not all, children are transfusion-dependent and folic acid supplements should be given to prevent deficiency due to chronic haemolysis.

Other red cell enzymopathies presenting in neonates

The other red cell enzymopathies are rare. The most important to be aware of in the neonatal period is triosephosphate isomerase

deficiency, which is autosomal recessive (Schneider 2000). One-third of cases present with neonatal haemolytic anaemia and this may be the only presenting feature at this age; the devastating neurological features of this disorder only become apparent 6–12 months later (Schneider 2000). Persistent haemolysis should therefore always be investigated.

Neonatal haemolysis due to haemoglobinopathies

The haemoglobinopathies, with the exception of α -thalassaemia major, do not usually present in the neonatal period. Occasional non-thalassaemic, structural α -globin and γ -globin gene mutations, which are clinically completely silent in adults and children, cause transient haemolytic anaemia (and diagnostic confusion!) in the neonate (see below). Symptoms and signs of the major β -globin haemoglobinopathies (sickle-cell disease and β -thalassaemia major) are rare in neonates, although modern techniques (e.g. high-performance liquid chromatography (HPLC), isoelectric focusing) allow the diagnosis to be made on neonatal blood samples where family studies indicate that both parents are carriers (Davies et al. 2000). Many countries and regions with a high prevalence of haemoglobinopathies, including the UK, have neonatal screening programmes to facilitate early diagnosis, which is particularly important in sickle-cell disease in order to start penicillin prophylaxis as soon as possible (Vichinsky et al. 1988; Davies et al. 2000; Karnon et al. 2000).

Alpha-thalassaemia major

Alpha-thalassaemia major occurs when all four α -globin genes on chromosome 16 are deleted (Higgs 1993). It predominantly affects families of south-east Asian origin and presents with mid-trimester fetal anaemia or hydrops fetalis which is fatal within hours of delivery (occasional babies have lived a few days). The only long-term survivors of α -thalassaemia major are those who received intrauterine transfusions (Dame et al. 1999; Singer et al. 2000; Sohan et al. 2002). In recent years there have been several reports of normal growth and development where intrauterine transfusion is commenced during the second trimester (Dame et al. 1999; Sohan et al. 2002); however, there is a high incidence of hypospadias in boys and other survivors have limb defects and/or severe neurological problems (Dame et al. 1999; Singer et al. 2000). If intrauterine transfusions are delayed until the anaemia is severe, neonatal pulmonary hypoplasia is a cause of early mortality. The diagnosis of α -thalassaemia major should be suspected in any case of severe fetal anaemia presenting in the second trimester and any case of hydrops fetalis with severe anaemia in which the parents come from south-east Asia (it is also seen occasionally in families who originate from India, the Middle East or the Mediterranean). Checking the blood counts of the parents will immediately identify whether they are at risk of having a child with α -thalassaemia major – both parents will be carriers of a chromosome 16 in which both of the two α -globin genes are deleted and so they will have hypochromic, microcytic red cell indices (MCV usually <74 fl and MCH usually <24 pg). The diagnosis of α -thalassaemia major is confirmed by haemoglobin electrophoresis or HPLC (which shows only Hb Barts and Hb Portland; HbF and HbA are absent); the blood film shows hypochromic, microcytic red cells with vast numbers of circulating nucleated red cells. Neonatal management of α -thalassaemia major has no impact on survival unless the baby has received intrauterine transfusions; for these transfused neonates, management is the same as for β -thalassaemia, i.e. lifelong red cell transfusions or bone marrow transplantation after the age of 2 years (Chik et al. 1998; Sohan et al. 2002).

Alpha- and gamma-globin chain structural abnormalities

Most α - and γ -globin gene variants are clinically silent. Occasional α -globin gene variants may cause haemolytic anaemia in the newborn because when the abnormal α -globin associates with γ -globin the resultant haemoglobin is unstable whereas when the variant α -globin associates with β -globin the resultant haemoglobin is stable. An example of this is Hb Hasharon: $\alpha^{214\text{Asp}\rightarrow\text{His}}\gamma_2$ is unstable; but as γ -globin chain production is physiologically switched off and β -globin chain production predominates, the $\alpha^{214\text{Asp}\rightarrow\text{His}}\beta_2$ produced is stable and the haemolytic anaemia completely resolves (Oski 1993). A similar principle occurs in the γ -globin variant HbF-Poole, which causes neonatal haemolytic anaemia that resolves as the switch from γ - to β -globin occurs (Lee-Potter et al. 1975). These variants can be identified by haemoglobin HPLC and are worth considering when commoner causes of haemolysis have been excluded.

Beta-thalassaemias and sickle-cell disease

Although these disorders are asymptomatic in neonates, if they are identified as a result of neonatal screening programmes, specialist advice should be sought as soon as possible. Babies with sickle-cell disease (homozygous sickle-cell disease, SC disease or S- β -thalassaemia) should be started on prophylactic penicillin V (62.5 mg twice daily) and folic acid (500 $\mu\text{g/kg/day}$) (Vichinsky et al. 1988). Babies with β -thalassaemia major usually start to require transfusion around the age of 6 months but benefit from folic acid supplementation until regular transfusions begin (Olivieri 1999).

Anaemia due to blood loss

Blood loss causing neonatal anaemia may be very obvious, e.g. a large subgaleal haematoma or rupture of the cord, or be concealed and easy to miss unless specifically sought (e.g. fetomaternal bleeds). Conventionally, the causes of anaemia due to blood loss are classified according to the timing of the blood loss – during fetal life, at the time of delivery or postnatally (see Table 30.4). In neonates admitted to hospital the most common cause of anaemia is blood loss secondary to iatrogenic blood letting.

Blood loss prior to birth

Twin-to-twin transfusion

Twin-to-twin transfusion occurs in monochorionic twins with monochorial placentas (Ch. 23) (Wee and Fisk 2002). Bleeding may be acute, particularly during the second stage of labour, or chronic (Wee and Fisk 2002). Chronic twin-to-twin transfusion can cause a marked difference in birthweight between twins, although recent studies show that the majority of twin pairs have a discordance in haemoglobin of <5 g/dl (Wee and Fisk 2002). The diagnosis is now usually made in fetal life and antenatal treatment may be required (Chs 9 and 23). The donor twin is smaller and may be pale and lethargic or have overt cardiac failure; the recipient twin may be plethoric, with hyperviscosity and hyperbilirubinaemia and may rarely have a haemoglobin as high as 30 g/dl. Where the haemoglobin/haematocrit are very high, disseminated intravascular coagulation (DIC) can occur. Management of DIC is described on page 776, and that of polycythaemia on page 767.

Fetomaternal haemorrhage

This may occur spontaneously or secondary to trauma, such as road traffic accidents or falls. Most spontaneous fetomaternal bleeds

occur in the third trimester or during labour. Fetomaternal bleeds may also be increased by invasive procedures such as fetal blood sampling and caesarean section. The degree of anaemia is variable and the clinical presentation depends on the amount and rate of blood loss. Most episodes involve very small quantities of blood (0.5 ml or less) but acute loss of >20% of the blood volume may cause intrauterine death, circulatory shock or hydrops (Giaccoia 1997). Diagnostic clues are anaemia at birth in an otherwise well term baby with no or minimal jaundice. The most useful diagnostic tests are a DAT to exclude immune haemolysis, a reticulocyte count to exclude red cell aplasia, a Kleihauer test on maternal blood to quantify the number of HbF-containing fetal RBCs in the maternal circulation and a blood film (Howarth et al. 2002). Where the baby has bled acutely just prior to delivery, the blood film is normochromic/normocytic with large numbers of nucleated red cells. In this situation, the haemoglobin may be normal at delivery but fall rapidly as haemodilution occurs. Where there is chronic blood loss, the baby is often well but may present with cardiac failure; the blood film in this situation is hypochromic/microcytic, the nucleated red cells are less prominent and the Kleihauer result may be difficult to interpret. Another point of note is that, where there is ABO incompatibility between the mother and baby, the fetal cells may be rapidly destroyed within the maternal circulation – a high index of suspicion of fetomaternal haemorrhage as a cause of neonatal anaemia is needed because it is important to perform the Kleihauer test as soon as possible, to increase the chance of detection of fetal cells. In many cases, an acute fetomaternal bleed supervenes upon chronic fetomaternal blood loss. In this situation, severe anaemia (Hb <5 g/dl) has been shown to confer a poor prognosis, as most survivors have evidence of brain injury, although there are notable exceptions (Giaccoia 1997).

Blood loss at or after delivery

Blood loss around the time of delivery is usually due to obstetric complications, including placenta praevia, placental abruption or incision of the placenta during caesarean section. Blood loss in this situation is from the maternal circulation, although the fetus can be subject to hypoxia as a result. Rarely, a vasa praevia is present, and is inevitably torn when the membranes rupture, leading to severe fetal blood loss. This can easily be missed because the volume of blood is relatively small in obstetric terms and it is not possible to distinguish fetal from maternal blood by eye. The incidence of vasa praevia is estimated to be around 1:2500 and the condition carries a high fetal mortality. The presence of a vasa praevia can be detected antenatally with a colour Doppler vaginal ultrasound but this is not routine practice; if a vasa praevia is found then the baby should be delivered by caesarean section before membrane rupture.

Haematological changes occur after massive internal bleeding in the baby, e.g. subaponeurotic or retroperitoneal bleeding, and may be particularly severe where there is damage to the liver. While most cases of internal bleeding are associated with traumatic delivery, it is important to search for any underlying bleeding diathesis in such babies, particularly haemophilia A or B and vitamin K deficiency. Inherited and acquired coagulation disorders that may present with bleeding at birth or during the neonatal period are discussed on pages 775–776.

Anaemia of prematurity

Pathogenesis

The haemoglobin falls after birth in all newborns, regardless of gestational age. This normal physiological fall in haemoglobin is

greater in preterm than in term neonates and has been termed 'physiological anaemia of prematurity' since it does not appear to be associated with any abnormalities in the baby. The pathogenesis is not fully elucidated but contributory factors include the reduced red cell lifespan of fetal erythrocytes, the relatively low erythropoietin concentration and the rapid growth rate (Osaki 1993). In practice, perhaps because of routine supplementation of preterm neonates with folic acid and iron, nutritional deficiency rarely plays a role (Fuller et al. 1992; Griffin et al. 1999; Rao and Georgieff 2002). On the other hand, for the majority of preterm infants in hospital, iatrogenic blood letting for diagnostic tests contributes to this physiological process. The clinical significance of anaemia of prematurity is mainly that the need for 'top-up' transfusion in preterm infants can be reduced if clinicians are aware of the normal nadir in erythropoiesis in neonates and the available measures to prevent the anaemia becoming severe.

Diagnosis

In a well term infant, the nadir in haemoglobin is as low as 9.4–11 g/dl and occurs at 8–12 weeks of age (see Table 30.2); for a preterm infant, the nadir in haemoglobin occurs earlier (4–8 weeks of age) and is lower (6.5–9 g/dl). The diagnosis is usually straightforward – a well preterm baby has a slowly falling haemoglobin with a completely unremarkable blood film showing normochromic/normocytic red cells, slightly low reticulocytes ($20 \times 10^9/l$) and no nucleated red cells.

Management

There are three facets to the management of anaemia of prematurity. The first is to exclude other causes of anaemia using clinical features and a diagnostic algorithm (see p. 762, Fig. 30.1). Secondly, a decision whether or not to transfuse should be made (the indications and principles of neonatal transfusion are discussed in detail on pp. 782–785). Thirdly, with increasing recognition of potential transfusion hazards, amelioration of neonatal anaemia to reduce the need for transfusion has become extremely important.

The role of erythropoietin and haematinics

The severity of anaemia of prematurity and thereby the need for red cell transfusion can be reduced by a combination of the following approaches:

- limiting iatrogenic blood loss by appropriate use of blood tests (Lin et al. 2000)
- iron and folate supplementation for all preterm infants:
 - iron 3 mg/kg/day from 4–6 weeks of age (a pragmatic approach is to give 1 ml of sodium ironedetate (Sytron) once daily) or iron-fortified formula with 0.5–0.9 mg/dl iron (Griffin et al. 1999; Rao et al. 2002; Haiden et al. 2006)
 - folic acid 50 µg daily or 500 µg once weekly (Fuller et al. 1992)
- judicious use of erythropoietin (Vamvakas and Strauss 2001; Garcia et al. 2002).

The many controlled trials of erythropoietin for prevention of neonatal anaemia have been extensively reviewed (Ohls 2002), including two meta-analyses (Vamvakas and Strauss 2001; Garcia et al. 2002), and are only briefly summarised here. Recombinant erythropoietin is biologically effective in that it stimulates erythropoiesis in all preterm infants and there is no evidence of erythropoietin insensitivity. Erythropoietin is also able to reduce red cell transfusion requirements in preterm infants (Vamvakas and Strauss 2001;

Garcia et al. 2002; Maier et al. 2002; Meyer et al. 2003; Haiden et al. 2006). However, in most studies there is no evidence to support the clinical effectiveness of erythropoietin, i.e. that it reduces the number of transfusions to an extent which demonstrably reduces the hazards of transfusion. At best, the studies show that erythropoietin reduces the number of transfusions in relatively well infants with low transfusion requirements (Vamvakas and Strauss 2001; Garcia et al. 2002; Meyer et al. 2003; Haiden et al. 2006). One study has shown that the use of erythropoietin together with careful nutritional supplementation and judicious use of laboratory tests to reduce iatrogenic blood loss can halve the transfusion requirements in a cohort of sick extremely-low-birthweight neonates (Haiden et al. 2006). However, most studies have shown that, even in high doses, the erythropoietin-mediated increase in red cell production is unable to increase sufficiently to cope with the need for frequent phlebotomy and multiple transfusions in sick preterm infants (Donato et al. 2000; Ohls et al. 2001). Despite its marginal role in reducing transfusion requirements, erythropoietin may become more important again if worries over the safety of blood transfusion lead to reduced availability and parental acceptance of red cell transfusion. At present, the main therapeutic roles for erythropoietin in neonates are:

- in preventing anaemia in infants who have received intrauterine transfusions for alloantibody-mediated anaemia (Zuppa et al. 2009)
- in a non-emergency situation where red cell transfusions are against the parents' wishes and are not felt to be absolutely essential to save the life of the baby (e.g. preterm babies of Jehovah's witnesses) (Horan and Stutchfield 2001).

An effective dose of recombinant erythropoietin in this setting is 300 µg/kg as a single subcutaneous injection three times per week starting in the first week of life. Epoetin-β should be used in view of the potential risk of red cell aplasia described (in adults) with epoetin-α, the alternative form of recombinant erythropoietin (Casadevall et al. 2002). This is because the haemoglobin does not start to rise until about 10–14 days after erythropoietin has been commenced. In addition, iron supplements (Sytron, as above) should be started as soon as possible, to prevent the rapid development of iron deficiency in erythropoietin-treated infants (the dose may need to be increased up to a maximum of 9 mg/kg if iron deficiency develops on the standard dose of Sytron) (Bechensteen et al. 1993).

A simple diagnostic approach to neonatal anaemia

Red cell disorders associated with neonatal or fetal anaemia present in three main ways: with a low haemoglobin (anaemia), with jaundice due to haemolysis or with hydrops. Table 30.4 lists the most common causes of anaemia, and the most common haematological causes of jaundice and hydrops are shown in Table 30.7 and Table 30.5, respectively. A diagnostic algorithm to help identify the most likely cause of neonatal hyperbilirubinaemia and the investigations which are most useful is shown in Figure 30.2. This is based on simple observations and simple tests available in almost all haematology laboratories. When in doubt about the best investigations to use and the interpretation of the results, discussion with a haematologist at an early stage should be helpful.

Polycythaemia

For both term and preterm infants, polycythaemia can be defined as a central venous haematocrit of >0.65. At haematocrits in excess

Table 30.7 Haematological causes of neonatal jaundice

Immune

α-thalassaemias (α-thalassaemia major; severe HbH disease) γ-thalassaemias (e.g. Hb Hasharon) Other: sickle-cell syndromes (occasionally)
Infection
Bacterial Viral, e.g. cytomegalovirus, rubella, herpes simplex Protozoal, e.g. <i>Toxoplasma</i> , malaria, syphilis

Table 30.8 Causes of neonatal polycythaemia

Intrauterine growth restriction Maternal hypertension Maternal diabetes Chromosomal disorders: trisomy 21, 18 or 13 Twin-to-twin transfusion Delayed clamping of the cord Endocrine disorders: thyrotoxicosis, congenital adrenal hyperplasia

of 0.65, there is an exponential rise in blood viscosity (Werner 1995). However, even at haematocrits >0.70, only a minority of neonates exhibit clinical signs of hyperviscosity. The clinical manifestations include lethargy, hypotonia, hyperbilirubinaemia and hypoglycaemia (Watts and Roberts 1999). Polycythaemia may also be a contributory factor in neonatal seizures, stroke, renal vein thrombosis and necrotising enterocolitis (NEC) (Hakanson and Oh 1977). Causes of polycythaemia are shown in Table 30.8. Treatment of neonatal polycythaemia is controversial and is probably not necessary in infants with very minor symptoms (e.g. borderline hypoglycaemia or poor peripheral perfusion). However, most of the evidence supports active management of infants with a haematocrit >0.65 in association with symptoms or signs indicative of an adverse long-term outcome (e.g. refractory hypoglycaemia, neurological signs). For these infants, partial exchange transfusion using a crystalloid solution such as normal saline should be performed to reduce the haematocrit to 0.55 (Watts and Roberts 1999). There is no evidence to support the use of fresh frozen plasma (FFP) or albumin (Wong et al. 1997) for this procedure, both of which carry the risk of transfusion-transmitted infection.

White cell disorders

Introduction and normal values

Apart from alterations in the numbers of white blood cells in response to infection, disorders of white cells are not common in neonates. Nevertheless, some diagnostic dilemmas do present in the neonatal period, in particular the causes and investigation of neutropenia and

how to identify rare disorders such as congenital leukaemia (both described below). However, there is often a lot of very useful information that can be discovered just from looking carefully at the morphology of the white blood cells on a neonatal blood film. Not only can an early diagnosis of bacterial infection often be made in this way, but also there may be indicators of the type of bacterial infection, of NEC, of congenital viral infections, or even of rare genetic and metabolic disorders.

Normal values

Neutrophil and monocyte counts vary over the first few days of life even in healthy babies, increasing for the first 12 hours and then falling to a nadir at 4 days of age. Normal values for neutrophils at birth are also affected by other factors, including antenatal history, perinatal history and ethnic origin. The neutrophil count is higher in capillary samples and after vigorous crying; it is lower in neonates of African origin. All of the other types of white blood cell found in adult blood are also present in the newborn (see [Table 30.2](#)). Conversely, some cell types not found in healthy adults are seen in healthy preterm babies – these include blast cells, other early myeloid cells, nucleated red cells and even occasional megakaryocytes.

Neutropenia

Definition and causes of neonatal neutropenia

Transient neutropenia is fairly common in preterm neonates but is uncommon in term infants. The normal values for neutrophil counts vary both with gestational age and with postnatal age, particularly over the first few days of life. A pragmatic approach is to consider a neutrophil count at birth of $<2 \times 10^9/l$ as abnormal and worth monitoring and a neutrophil count during the first month of life of $<0.7 \times 10^9/l$ as significant enough to merit further investigation. The principal causes of neonatal neutropenia are shown in [Table 30.9](#). The commonest cause in preterm neonates is neutropenia in association with IUGR and/or maternal hypertension ([Koenig and Christensen 1989](#)), while in term infants bacterial or

viral infection is the usual explanation. Other important causes of neutropenia, as they may be the cause of severe neonatal infection, are alloimmune neutropenia and congenital neutropenia due to failure of neutrophil production (e.g. Kostmann syndrome).

Neutropenia and infection

Any bacterial infection can cause acute neutropenia. Where this is short-lived (6–12 hours) it is a normal response, but neutropenia lasting >12 hours in the setting of acute bacterial infection may be a poor prognostic sign. Examination of the blood film is often helpful in differentiating neutropenia secondary to bacterial infection from viral infection or IUGR. The classical signs of acute bacterial infection are the presence of an increased percentage of band neutrophils and toxic granulation of immature and mature neutrophils, followed after 1–2 days by a mature neutrophilia and after 3–5 days by eosinophilia. By contrast, there is no increase in band cells or toxic granulation in viral infections; instead, atypical ‘viral’ lymphocytes are seen, particularly in congenital CMV infection, where they may persist for several months.

Neutropenia and intrauterine growth restriction

The commonest cause of neutropenia in preterm infants is IUGR and/or maternal hypertension or maternal diabetes. In these disorders, neutrophil production is reduced because of inadequate numbers of neutrophil progenitors; most affected neonates also have thrombocytopenia and increased erythropoiesis (polycythaemia and/or increased circulating nucleated red cells) ([Watts and Roberts 1999](#)). The exact pathogenesis is unknown but evidence suggests that the haematological abnormalities are secondary to fetal tissue hypoxia ([Watts and Roberts 1999](#)). The neutropenia resolves spontaneously, usually starting to recover 2–3 days after birth. However, both the duration and the severity of the neutropenia are directly related to the severity of the IUGR/maternal hypertension ([Koenig and Christensen 1989](#); [Watts and Roberts 1999](#)). The main clinical significance of this form of neutropenia is firstly that recognition of its natural history prevents unnecessary treatment and investigations, and secondly that affected neonates do tend to have a ‘blunted’ neutrophil response to infection, i.e. the neutrophil response is both delayed and sometimes inadequate, which may lead to an increased frequency and duration of bacterial infections. There are no specific diagnostic tests for this form of neutropenia but clues that this is the explanation for the neutropenia are the clinical history, the concomitant presence of a platelet count $<150 \times 10^9/l$, an increased number of circulating nucleated RBCs (usually $>20/100$ white cells) and the severity (usually the neutrophil count is $>0.3 \times 10^9/l$). Neither of the recombinant haemopoietic growth factors available for therapeutic use in stimulating neutrophil production (G-CSF and GM-CSF) has been shown to be of clinical value in the treatment or prevention of IUGR-associated neutropenia ([Carr et al. 2003](#)).

Alloimmune neutropenia

Alloimmune neutropenia is the neutrophil equivalent of HDN and alloimmune thrombocytopenia. It occurs when fetal neutrophils express paternally derived neutrophil-specific antigens which are absent on maternal neutrophils and against which the mother produces IgG neutrophil alloantibodies ([Maheshwari et al. 2002](#)). The causative antibodies are usually anti-NA1 or anti-NA2 ([Stroncek 2002](#)). It is widely quoted that alloimmune neutropenia affects 3% of all deliveries ([Maheshwari et al. 2002](#)), although relatively few cases are reported and in our experience this is a very uncommon

Table 30.9 Causes of neonatal neutropenia

Congenital leukaemia

clinical problem. This suggests that, while the causative antibodies may be present in 3% of women, most neonatal cases are so mild that the signs do not merit medical attention. Therefore, from a practical perspective, the importance of neonatal alloimmune neutropenia is that it should be thought of as a possible cause of neutropenia in any neonate with a severe bacterial infection together with a neutropenia which persists for more than 3 days despite appropriate antibiotic treatment. Clinically significant neonatal alloimmune neutropenia presents in the first few days of life with fever and infections of the respiratory tract, urinary tract and skin, particularly due to *Staphylococcus aureus*. The diagnosis is made by demonstrating antineutrophil antibodies in the mother and baby which react against paternal, but not maternal, neutrophil antigens. The neutropenia is self-limiting, usually resolving within 1–2 months, and the mainstay of treatment is antibiotics. In severe cases, where there is clinical deterioration despite antibiotics, plasma exchange and/or G-CSF (10 µg/kg/day) may be useful.

Congenital and inherited neutropenias

All of the inherited and congenital neutrophil disorders are rare and are listed in Table 30.9. These should be sought where the neutropenia is prolonged, if there is a relevant family history or consanguinity, or if the baby has typical dysmorphic features (e.g. thumb/radial abnormalities in Fanconi's anaemia). The most likely of these to present in the neonatal period is severe congenital neutropenia (SCN), which used to be referred to as Kostmann syndrome; it is now recognised to be a heterogeneous group of conditions due to mutations in several different genes (Klein et al. 2007; Zeidler et al. 2009). SCN is defined as a condition in which neutrophil production is reduced due to an 'arrest' of differentiation at the myelocyte/promyelocyte stage. Infants with SCN usually present with severe infections within a few weeks of birth (Zeidler et al. 2009). Other clues to the diagnosis are that the neutropenia is marked (usually $<0.2 \times 10^9/l$) and there is often a marked compensatory monocytosis. SCN can be either autosomal recessive or autosomal dominant depending on the gene(s) which is/are mutated. The most common genetic cause is mutations of the elastase gene (*ELA2*) (Aprikan et al. 2004), which is autosomal dominant; the original Kostmann syndrome is due to mutations in *HAX1*, which is autosomal recessive (Klein et al. 2007). The diagnosis is made on the basis of the severity of the neutropenia, the bone marrow appearances, the clinical history and the absence of antineutrophil antibodies. Where mutational analysis is available, this may prove useful for establishing the diagnosis and for prenatal diagnosis.

Congenital leukaemias and haematological abnormalities associated with Down syndrome

Congenital leukaemias

Congenital leukaemia is rare but the diagnosis is usually straightforward. The most common types are acute monoblastic leukaemia and acute megakaryoblastic leukaemia (Bresters et al. 2002). The usual presentation is with clinical signs of anaemia and skin lesions caused by focal infiltration by leukaemic cells. Rapid clinical deterioration due to severe anaemia and thrombocytopenia is common. Congenital leukaemia may also present as 'blueberry muffin' baby or hydrops fetalis (Bowden et al. 1989). Diagnostic clues to congenital leukaemia are the concomitant presence of severe and worsening anaemia and thrombocytopenia in a sick baby, usually with a very high white blood cell count. The diagnosis is established by

examination of the blood film, which shows large numbers of primitive blast cells, and a bone marrow aspirate, bone marrow cytogenetics and immunophenotyping of the peripheral blood (or marrow) leukaemic cells. The prognosis is extremely poor; few are cured by chemotherapy, and bone marrow transplantation, which has been carried out successfully, may be the best option (Bajwa et al. 2001). Babies with Down syndrome may occasionally present with leukaemia but more often have a transient leukaemia known as transient myeloproliferative disorder or transient abnormal myelopoiesis (TAM) – see below (Roy et al. 2009).

Haematological abnormalities in neonates with Down syndrome and other trisomies

Haematological abnormalities are more common in neonates with chromosomal disorders, including Down syndrome, trisomy 13 and trisomy 18, all of which may be associated with pancytopenia. Most babies with Down syndrome have minor abnormalities (thrombocytopenia, neutrophilia or polycythaemia are the most common, but 5–10% have TAM).

TAM is frequently asymptomatic and is diagnosed when the blood count shows leukocytosis and the blood film is abnormal with increased numbers of circulating blast cells (Roy et al. 2009). Some babies develop signs of hepatic infiltration and abnormal liver function tests are frequently found. Mutations in GATA-1, a critical haemopoietic cell transcription factor, have recently been reported both in almost all neonates with TAM and in the megakaryoblastic leukaemia associated with Down syndrome (Wechsler et al. 2002; Hitzler et al. 2003; Roy et al. 2009). Usually, no treatment is indicated for TAM, which resolves by the age of 2–3 months in >70% of cases (Roy et al. 2009); occasionally neonates die from fulminant hepatic involvement and up to 30% will subsequently develop acute megakaryoblastic leukaemia within the first 5 years of life. For this reason, and because TAM is often asymptomatic, it is advisable to perform a full blood count and film on all neonates with Down syndrome (Roy et al. 2009).

Abnormal leukocytes in neonatal systemic disease

Careful examination of the blood film often provides clues to other underlying disorders in the newborn. As well as classical features of acute bacterial and viral infections, characteristic changes can be seen in fungal infection, where vacuolation of the neutrophils and monocytes may be prominent and fungi may be seen within the phagocytic cells. In NEC, neutrophil and monocyte vacuolation is almost always present and is usually a very early feature. A number of metabolic and storage disorders also produce changes in the appearance of leukocytes:

- leukocyte vacuolation in Pearson syndrome
- giant neutrophil granules in Chédiak–Higashi syndrome
- Alder Reilly leukocyte granules in Hunter syndrome, Hurler syndrome and Sanfilippo syndrome
- lymphocyte vacuolation in Wolman's disease, α -mannosidosis, sialidosis and Sanfilippo syndrome.

Haemostasis and thrombosis in the newborn

Introduction

Problems of disordered coagulation with or without obvious bleeding are relatively common in neonates, especially when they are

sick. Thrombotic problems are also increasingly recognised in neonates, and the number of genetic and acquired causes of thrombophilia that can be identified in neonates and their families is rising. Therefore, in order to request and interpret the most useful laboratory tests, and to treat appropriately, it is important to have a basic understanding of normal haemostasis and how it differs in neonates compared with in older infants and children.

Haemostasis, the process of normal blood coagulation, takes place via a series of complex interactions involving both activators and inhibitors of coagulation (Hutton et al. 1999). In general, defects in the coagulation proteins (such as the vitamin K-dependent factors), in platelet number or function, or in the fibrinolytic pathway are associated with an increased risk of bleeding. In contrast, defects in the naturally occurring anticoagulants (such as protein C) or in the vessel wall (such as damage from vascular catheters) are associated with thrombosis. However, in many cases, both pro- and anticoagulant abnormalities can occur at the same time, as seen, for example, in DIC.

The process can be summarised as follows. In the first stage, tissue factor (TF) binds to the coagulation factor VIIa, and the TF-VIIa

complex, by converting factor X to Xa, leads to the generation of small amounts of thrombin (Fig. 30.3A). In the second stage, amplification of the coagulation cascade occurs as the thrombin activates factor V and factor VIII, and the TF-VIIa activates factor IX, leading to rapid generation of more thrombin. Thrombin also activates factor XI, further amplifying its own generation (see Fig. 30.3B). Finally, thrombin converts fibrinogen to fibrin with subsequent cross-linking by factor XIII to stabilise the clot. The role of TF is of particular interest as it is produced not only by endothelial cells but also by monocytes (Mattsson et al. 2002). TF is increased by endotoxin and proinflammatory cytokines and so is likely to play an important role in the pathogenesis of sepsis-associated DIC (Osterud and Bjorklid 2001).

Platelets

The role of platelets in coagulation is also critical, as shown by the risk of severe bleeding in patients with thrombocytopenia. Endothelial damage leads to exposure not only of TF but also of collagen, which binds von Willebrand's factor (vWF) produced by the

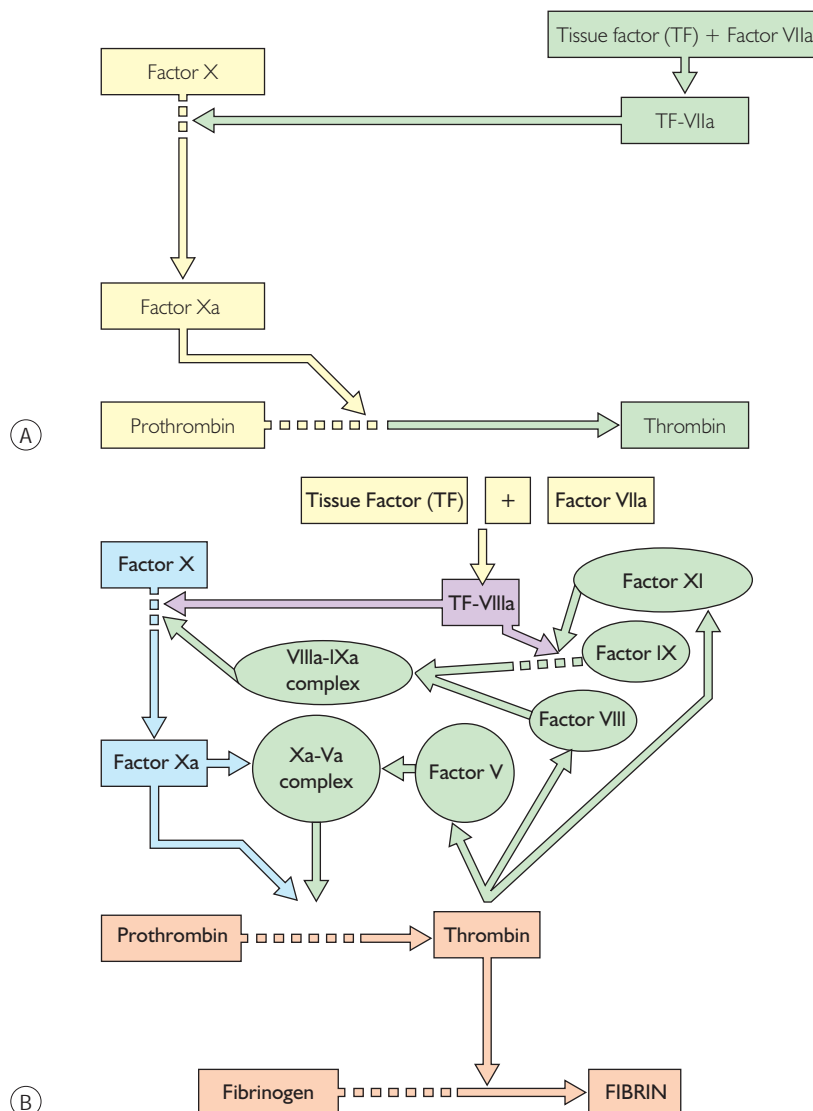

Fig. 30.3 A simplified scheme of the coagulation cascade. The first stage in the coagulation cascade is the binding of tissue factor (TF) to the coagulation factor VIIa. The TF-VIIa complex, by converting factor X to Xa, leads to the generation of small amounts of thrombin (A). In the second stage, amplification of the coagulation cascade then occurs as the thrombin activates factor V and factor VIII, and the TF-VIIa activates factor IX, leading to the rapid generation of more thrombin. Thrombin also activates factor XI, further amplifying its own generation (B). Finally, thrombin converts fibrinogen to fibrin with subsequent cross-linking by factor XIII to stabilise the clot.

endothelial cells. Platelets are first captured by the vWF via their glycoprotein 1b (Gp1b) receptors and are then 'tethered' by activation of their glycoprotein IIb/IIIa (GpIIb/IIIa) receptors, which bind to both vWF and fibrinogen. More and more platelets accumulate, followed by more vWF and fibrinogen, to form an occlusive platelet plug.

Regulation of the procoagulant process by endogenous anticoagulants and fibrinolysis

The procoagulant process is regulated by a large number of mechanisms. These include the natural anticoagulants (antithrombin; protein C/protein S/thrombomodulin), TF pathway inhibitor (TFPI) and the fibrinolytic pathway (Edstrom et al. 2000). The physiological importance of the natural anticoagulants is clear from the high risk of thrombosis in patients with deficiency of these factors. The main purpose of the natural anticoagulants is to limit the generation of thrombin and thereby prevent thrombosis. Antithrombin, heparin cofactor II and α_2 -macroglobulin are direct inhibitors of thrombin. The protein C/protein S/thrombomodulin pathway is also activated by thrombin and does not function in the absence of thrombin. Current models (Fig. 30.4) indicate that activation of protein C requires binding of protein C to two receptors on the endothelial surface, thrombomodulin and the endothelial protein C receptor, which then act as a molecular switch to limit the procoagulant activity of thrombin (Kottke-Marchant and Comp 2002). Activated protein C then forms a complex with protein S and the protein C/S complex cleaves and inactivates factors Va and VIIIa, thus switching off thrombin generation. Consequently, vascular endothelium plays a key role in haemostasis not only by providing the principal initiator of coagulation (TF) but also by switching off the process via thrombomodulin.

A further mechanism preventing sustained activation of the procoagulant pathway is TFPI, which limits TF-induced initiation of coagulation. Finally, the risks of uncontrolled thrombosis due to activation of the procoagulant process are limited by the

fibrinolytic pathway. Fibrinolysis controls fibrin deposition at the site of injury via the activity of the serine protease plasmin and by thrombin-activated fibrinolysis inhibitor (TAFI) (Bouma et al. 2001). Like other aspects of the haemostatic system, this pathway is subject to feedback control to provide a balance between coagulation and fibrinolysis. For example, fibrin itself stimulates release of tissue plasminogen activator (t-PA) and urokinase-type plasminogen activator, which convert plasminogen into plasmin. Plasmin rapidly digests both fibrin and fibrinogen, leading to the production of fibrin degradation products. Plasmin is also able to digest fibrin cross-linked by factor XIII, leading to the generation of D-dimers.

Developmental haemostasis

Coagulation proteins are synthesised by the fetus from the fifth week of gestation onwards (Andrew 1997). Levels gradually rise during fetal life but, with some exceptions (see below), do not reach adult values until several months after birth, even in term babies. Thus, 'normal values' in the neonate vary not only with gestational but also with postnatal age (Appendix 2). Coagulation proteins do not cross the placenta, or do so in very small amounts, and therefore need to be independently synthesised by the fetus. However, fetal coagulation factor synthesis can be affected by maternal factors (e.g. warfarin, severe maternal vitamin K deficiency).

There are few data about the normal ranges of the coagulation factors at different gestational ages. In addition, the results can be difficult to interpret as there are differences between the levels measured in cord blood and the levels collected from fetal blood by fetoscopy at the same gestational age, perhaps because of activation of coagulation during birth (Andrew et al. 1987). The published data for coagulation factor levels in preterm neonates are for those born between 30 and 36 weeks' gestation (Appendix 2) (Andrew et al. 1988). Corresponding data are also available for term babies (Appendix 2) (Andrew et al. 1987). Data for babies at <30 weeks' gestation derive from fetoscopy samples and show that the levels of the vitamin K-dependent factors (II, VII, IX and X) and of factors XI and XII are all low (<40% of adult values) and remain so during the first month of life (Reverdiau-Moalic et al. 1996). By contrast, even in preterm babies (<30 weeks), levels of factor V, factor XIII and fibrinogen are normal at birth and levels of factor VIII and vWF are normal or increased.

Blood platelet counts at birth in term and preterm neonates are within the normal adult range (Roberts and Murray 2001). Many studies have found impaired function of neonatal platelets in vitro in term and preterm infants; the most consistent abnormalities are reduced aggregation in response to adrenaline (epinephrine), adenosine diphosphate and thrombin. Their significance in clinical practice is unclear since the bleeding time tested with adult and neonatal devices is normal in term and preterm infants (<135 seconds) (Stuart and Graeber 1998) and bleeding problems associated with abnormal platelet function are rare in neonates. There are also important gestational and postnatal age-related changes in the levels of the fibrinolytic and natural anticoagulant pathways.

Diagnostic approach to bleeding in neonates

Clinical presentation of bleeding disorders

The clinical presentation and likely cause(s) of bleeding in neonates depend on gestational age and whether the infant is sick or well. Particular patterns of bleeding may also suggest the underlying

Fig. 30.4 Inactivation of activated factor VIII and factor V by the protein C/S pathway. The protein C/protein S/thrombomodulin pathway is activated by thrombin. The activation of protein C requires binding of protein C to two receptors on the endothelial surface, thrombomodulin (TM) and the endothelial protein C receptor (EPCR), which then act as a molecular switch to limit the procoagulant activity of thrombin. The activated protein C (APC) then forms a complex with protein S, and the protein C/S complex cleaves and inactivates factors Va and VIIIa, thus switching off thrombin generation.

diagnosis, such as bleeding from the umbilical cord stump in factor XIII deficiency and bleeding after circumcision in haemophilia. The most common sites of bleeding in preterm neonates are oozing from venepuncture sites, pulmonary haemorrhage, gastrointestinal bleeding and intracranial haemorrhage. In term neonates, cephalohaematomas are commonly seen following both normal and forceps deliveries. Subarachnoid (subgaleal) haemorrhages (Ch. 40.3) are increased following vacuum extraction (Wen et al. 2001) but in otherwise healthy neonates these bleeding manifestations are unlikely to be markers of disordered haemostasis. However, a neonate with a large subaponeurotic or subdural haemorrhage should be screened for coagulation defects (Davis 2000). Magnetic resonance imaging studies have shown that small peritentorial subdural collections are common after a normal delivery; in haemophilia it is probably the case that these continue to enlarge over the ensuing days, because the blood does not clot. Germinal matrix haemorrhage/intraventricular haemorrhage (GMH-IVH) in term babies is also rare and should point to a possible coagulation defect. GMH-IVH and thalamic haemorrhage in term babies is often secondary to venous thrombosis (Ch. 40.3) and a thrombophilia screen may be indicated. In any infant with abnormal bleeding, blood tests to identify the most likely cause should always be accompanied by a thorough clinical assessment, including sites of possible occult bleeding, and a careful history, including maternal/infant drugs (was vitamin K given?) and questions to elucidate a family history of bleeding disorders.

Screening tests for bleeding disorders

Nearly all significant bleeding disorders in neonates can be identified using simple screening tests, as summarised below. Notable exceptions are factor XIII deficiency (which requires a specific assay) and platelet function disorders (which require specialised tests and are usually performed after the neonatal period, because of the difficulties of sample size and data interpretation in neonates). Where an inherited defect is suspected or where bleeding and coagulation assay derangement are severe, it is extremely important to test both parents for coagulation abnormalities. There are several reasons for this: there is considerable interindividual variation in factor levels in neonates; there is also overlap between the deficiency states and the lower limit of normal, particularly in preterm neonates, when levels of many factors are physiologically low; and, finally, it is often difficult to obtain good-quality neonatal samples free from *in vitro* activation or contamination with heparin.

The most useful screening tests in neonates are:

- prothrombin time (PT) – this predominantly measures the activity of factors II, V, VII and X
- activated partial thromboplastin time (APTT) – this predominantly measures the activity of factors II, V, VIII, IX, X, XI and XII
- thrombin time (TT) – this tests for deficiency or dysfunction of fibrinogen
- quantitative fibrinogen assay
- platelet count.

The results of these tests along with the clinical history will guide subsequent investigation. A reptilase time (so named because snake venom is used in the test) can also be very helpful; it assesses the same components as a TT but is unaffected by heparin and so is useful when heparin contamination from an indwelling line is suspected. Bleeding times are generally unhelpful in neonates and have been abandoned in most centres. Instead, platelet function is usually assessed by platelet aggregometry using a limited range of agonists and by a newly developed machine which measures

platelet-dependent clot formation in whole blood (the platelet function analyser PFA-100) (Israels et al. 2001).

Interpretation of coagulation screen results

Interpretation can often be difficult, particularly in preterm babies and in those who are sick, because the cause is usually multifactorial. Broadly there are two ways to approach this: firstly, by considering the causes for an abnormality in each individual test (Table 30.10), and, secondly, by considering the pattern of results expected in the most common, clinically important conditions. These are discussed in more detail in the sections on inherited and acquired disorders (pp. 774–778).

Inherited coagulation disorders

While inherited coagulation disorders are rare, some of the most severe disorders may present in the neonatal period with life-threatening bleeding in otherwise healthy babies. The commonest are the X-linked disorders factor VIII deficiency (haemophilia A), which has a frequency of 1 in 5000 male births, and factor IX deficiency (haemophilia B), which occurs in 1 in 30 000 male births (Kulkarni and Lusher 2001). It is important to note that one-third of cases have no family history of haemophilia as they are due to new mutations. The other inherited coagulation disorders which may present with bleeding in the neonatal period are the severe

Table 30.10 Causes of abnormal coagulation tests in the newborn

Prolonged APTT alone	Inherited deficiency of factor VIII, factor IX, factor XI, factor XII Heparin (therapeutic or heparin contamination*)
Prolonged PT alone	Inherited deficiency of factor VII Vitamin K deficiency (haemorrhagic disease of the newborn) Warfarin
Prolonged TT alone	Low fibrinogen Artefact: contamination with heparin from line or sample bottle*
Prolonged APTT + PT	Inherited deficiency of factor II, factor V, factor X Liver disease
Prolonged APTT, PT and TT	Inherited deficiency of fibrinogen Disseminated intravascular coagulation Severe liver disease
Normal APTT, PT	Factor XIII deficiency and TT Platelet defect: thrombocytopenia or rare platelet function abnormality (e.g. Bernard Soulier syndrome)

APTT, activated partial thromboplastin time; PT, prothrombin time; TT, thrombin time.

*The effect of heparin contamination can be distinguished by checking the reptilase time on a coagulation sample; where a prolonged TT and/or a prolonged APTT is due to heparin contamination, the reptilase time will be normal, but where a prolonged TT or APTT is due to a true coagulation defect, the reptilase time will be abnormal.

forms of von Willebrand disease (vWD; type 3 and occasionally type 2b), factor XIII deficiency and deficiencies of factors II, V, VII, X and XI, which are all autosomal recessive and relatively rare.

Haemophilia A: factor VIII deficiency

Clinical presentation

Although the majority of cases of haemophilia A present in the second year of life, a recent review of the literature found that 3.5–4% of all boys with haemophilia born in countries with a good standard of healthcare suffer from intracranial haemorrhage in the neonatal period (Kulkarni and Lusher 1999; Looney et al. 2007). As discussed above, the problem is probably due to a slow expansion of a small subdural haemorrhage associated with delivery and it is sensible to warn parents about the signs of intracranial haemorrhage if their baby is known to have haemophilia. Other, slightly less common sites of bleeding typical of neonatal haemophilia are subgaleal collections, bleeding postcircumcision and bleeding from venous or arterial puncture sites (Kulkarni and Lusher 1999, 2001). Prolonged bleeding from the umbilical cord is less common and haemarthroses are rare. Haemorrhage into major organs such as the liver, spleen or lungs is also uncommon but has been reported in up to 5% of cases (Kulkarni and Lusher 2001).

Diagnosis

The diagnosis of haemophilia A in the neonatal period should be straightforward on either a cord blood or peripheral blood sample. The characteristic finding is a prolonged or very prolonged APTT together with a normal PT, TT, platelets and fibrinogen. The diagnosis is then established by measurement of factor VIII clotting activity, which is always reduced in haemophilia A (all other coagulation factors, including von Willebrand antigen, are normal). Clinically, the severity of the disease is classified according to the level of factor VIII activity: levels of <2% (i.e. <0.02 IU/ml) are classified as severe disease, 2–10% (0.02–0.1 IU/ml) as moderate disease, and >10% (>0.1 IU/ml) as mild haemophilia. Where there is a family history of haemophilia A, the diagnosis may be established prenatally by a variety of methods; most families choose early diagnosis by mutational analysis of the factor VIII gene on a chorionic villus biopsy in the first trimester (Kadir 1999).

Neonatal management

Acute management of the bleeding neonate with haemophilia requires intravenous administration of recombinant factor VIII. If absolutely necessary, FFP or cryoprecipitate (15–20 ml/kg) may be used for major haemorrhage if there is significant delay. The usual treatment dose of factor VIII in neonates is 50–100 units/kg intravenously twice daily (Kulkarni and Lusher 2001; British Committee for Standards in Haematology, Haemostasis and Thrombosis Task Force 2002). Since the half-life of factor VIII is shorter in children than in adults, more frequent dosing or a continuous factor VIII infusion may be required. The dose should be adjusted by monitoring plasma factor VIII activity to achieve factor VIII levels of 100% (1.0 IU/ml) (Kulkarni and Lusher 2001; British Committee for Standards in Haematology, Haemostasis and Thrombosis Task Force 2002). This is done by measuring plasma factor VIII activity and close liaison with a specialist haematologist. For neonates with intracranial bleeding, treatment with factor VIII should continue for at least 2 weeks. Note that venepuncture should be performed with great care in all haemophiliac neonates and arterial punctures should be avoided. In addition, lumbar punctures should be avoided unless essential for clinical management, and, if necessary, should be done by an experienced person in the presence of factor

VIII cover. Fibrin glue may be useful in circumcision-associated bleeds.

Once the baby is ready for discharge it is vital to provide specialist family support and follow-up through a haemophilia centre. In the UK, all children are registered with such a centre and have access to clinical nurse specialists and haematologists with expertise in haemophilia. The UK Haemophilia Centres Doctors' Organization also publishes regularly updated guidelines on the recommended products for treatment of patients with hereditary coagulation disorders (United Kingdom Haemophilia Centre Doctors' Organization 2008). The Haemophilia Society provides very useful practical support and advice for families with affected children.

Prenatal management and delivery

For patients diagnosed prenatally, the best mode of delivery is controversial and accurate data about the risks are very limited. It is clear that significant haemorrhage may occur whatever the mode of delivery; in particular, there is no evidence that elective caesarean section eliminates the risk of bleeding (Kulkarni and Lusher 2001). Vaginal delivery is regarded as safe provided there are no difficulties anticipated (Looney et al. 2007); however, vacuum extraction should be avoided because several studies have shown a high rate of subgaleal bleeds and cephalohaematomas in this situation (Towner et al. 1999; Kulkarni and Lusher 2001). In known or suspected haemophiliac newborns, cord blood should always be taken for a coagulation screen and factor VIII level to confirm the diagnosis. Oral vitamin K should be given at birth because the intramuscular route should be avoided in view of the risk of haematoma formation. The role of prophylactic factor VIII administration to haemophiliac newborns following difficult delivery to reduce the risk of intracranial bleeding is controversial (Buchanan 1999; Kulkarni and Lusher 2001; Looney et al. 2007; United Kingdom Haemophilia Centre Doctors' Organization 2008). The risk of intracranial haemorrhage at around the time of birth in baby boys with haemophilia is ~4%; at least half have significant sequelae (Ljung 2007). Any intervention that could reduce this morbidity deserves consideration. Magnetic resonance imaging studies in normal babies have shown that small peritentorial subdural haematomas are common (Looney et al. 2007). In a haemophilic baby boy, the collection is likely to continue to expand over several days because the blood will not clot, and hence parents should be warned to return to the hospital if they have any concerns (such as poor feeding, abnormal movements). The main disadvantage of prophylactic factor VIII is that it may increase the risk of inhibitor formation, leading to major problems with treatment later in childhood. Recent consensus advice from the European Paediatric Network for Haemophilia Management and the International Network of Pediatric Hemophilia recommended routine cranial ultrasound of all newborns born to known or suspected haemophilia carriers soon after delivery and administration of factor VIII only to those with signs of intracranial haemorrhage, while recognising that ultrasound will not detect all types of intracranial haemorrhages, particularly small peritentorial bleeds (Ljung 2007).

Haemophilia B: factor IX deficiency

Haemophilia B is clinically indistinguishable from haemophilia A. From the diagnostic point of view, both diseases cause an isolated prolonged APTT, but the diagnosis of factor IX deficiency is made by demonstrating a low factor IX level. Occasional diagnostic confusion may arise with mild factor IX deficiency, as factor IX levels also fall in liver disease and vitamin K deficiency. Although this is usually

straightforward to resolve since there will be concomitant reductions in the other vitamin K-dependent factors in this situation, it is important to recheck factor IX levels at 6 weeks and 6 months of age if in doubt.

Management of factor IX deficiency is similar to that of factor VIII deficiency. Treatment of bleeding is with recombinant factor IX concentrate. The usual dose is 100 units/kg intravenously once daily, and treatment should be monitored to achieve a factor IX level of 80–100% (1.0 IU/ml) (Kulkarni and Lusher 2001; British Committee for Standards in Haematology, Haemostasis and Thrombosis Task Force 2002). As for haemophilia A, treatment for intracranial haemorrhage should be continued for at least 2 weeks (Kulkarni and Lusher 2001). Similarly, lumbar punctures should be avoided where possible and venepunctures kept to a minimum. Recommendations for prenatal management are as for haemophilia A.

von Willebrand disease in neonates

vWD is caused by quantitative or qualitative defects in vWF. It is the commonest inherited bleeding disorder, affecting around 1% of the population (Castaman et al. 2003). There are several types of vWD, each of which has different clinical and genetic characteristics, but only two forms of the disease present in the neonatal period. Type 2b vWD is autosomal dominant and presents with thrombocytopenia; bleeding is uncommon. Type 3 vWD is the most severe form of the disease (Ikenboom 2001). It is autosomal recessive and has a clinical phenotype similar to haemophilia, as levels of both vWF and factor VIII are low. The diagnosis is made by measuring vWF and factor VIII, and determining the pattern of vWF multimers; clinical clues are the presence of a haemophilic pattern of bleeding in girls or families without X-linked inheritance and a poor response to factor VIII concentrates. Type 3 vWD is currently treated with intermediate-purity factor VIII (Haemate-P is the most commonly used product) (British Committee for Standards in Haematology, Haemostasis and Thrombosis Task Force 2002).

Factor XIII deficiency

Factor XIII deficiency is a rare autosomal recessive disorder in which the routine diagnostic coagulation screen is normal. It usually presents clinically with delayed bleeding from the umbilical cord during the first 3 weeks of life (Anwar and Miloszewski 1999; Anwar et al. 2002). Intracranial haemorrhage has been reported in up to 30% of neonates with homozygous factor XIII deficiency (British Committee for Standards in Haematology, Haemostasis and Thrombosis Task Force 2002). The diagnosis is made by measuring clot solubility in 5 M urea solution as a screening test, followed by a specific factor XIII assay; molecular tests for the common mutations are also available (Smith 1990). The treatment of bleeding associated with factor XIII deficiency is factor XIII concentrate; cryoprecipitate (10 ml/kg) can be used prior to establishment of the diagnosis or where the specific concentrate is unavailable. Infants with homozygous factor XIII deficiency have a lifelong risk of intracranial haemorrhage, and current guidelines recommend monthly factor XIII to reduce this risk (United Kingdom Haemophilia Centre Doctors' Organization 2008).

Other inherited coagulation factor deficiencies

A number of rare coagulation deficiencies may present in neonates with bleeding or unexplained prolongation of coagulation tests. The majority are autosomal recessive and so a history of parental consanguinity is relatively common. Factor VII deficiency can

produce a very severe bleeding disorder with a high incidence of intracranial haemorrhage. In some cases, factor VII has been shown to cross the placenta and in this way delay haemorrhage in severe factor VII deficiency until after birth. Recombinant factor VIIa is now available to treat this disorder but must be given at frequent intervals as it has a very short half-life (Chuansumrit et al. 2002). Factor XI deficiency is most frequent in Ashkenazi Jews and presents in a similar way to haemophilia. There are a number of rare congenital fibrinogen disorders, including dysfibrinogenemias and hypo/fibrinogenemia. They may present with umbilical stump bleeding but other sites of haemorrhage are extremely unusual in neonates. It is important to note that one of the commonest inherited causes of an isolated prolonged APTT in a healthy baby with no signs of bleeding is factor XII deficiency; despite what is often a markedly prolonged APTT, affected individuals have no clinically apparent bleeding disorder throughout life! Guidelines on the selection and use of therapeutic products to treat all hereditary bleeding disorders are produced by the UK Haemophilia Centre Doctors' Organisation and are regularly updated (United Kingdom Haemophilia Centre Doctors' Organization 2008).

Acquired disorders of coagulation

Vitamin K deficiency

Levels of the active forms of the vitamin K-dependent pro-coagulant factors (factors II, VII, IX and X), and of the natural anticoagulants protein C and protein S, are physiologically low at birth. There are many reasons for this. Vitamin K is essential for γ -carboxylation of these proteins, which converts them to their active form: placental transfer of vitamin K is insufficient to build up adequate stores in the neonate (Zipursky 1999); breast milk has a low vitamin K content; and bacterial vitamin K synthesis is lacking in the sterile neonatal gut. In neonates, vitamin K deficiency can lead to haemorrhagic disease of the newborn, now more commonly referred to as vitamin K-deficiency bleeding (VKDB) and comprehensively reviewed in two recent articles (van Winkel et al. 2008; Shearer 2009). It can be classified into early, classical and late disease according to the timing or presentation and the clinical features.

Early VKDB

This presents in the first 24 hours of life, usually with severe haemorrhage, including gastrointestinal bleeding and intracranial haemorrhage. It is caused by severe vitamin K deficiency in utero, usually as a result of maternal medication that interferes with vitamin K, e.g. anticonvulsants (phenobarbital, phenytoin), antituberculous therapy and oral anticoagulants. Guidelines for prevention of early VKDB are discussed below.

Classical VKDB

This presents at 2–7 days old in babies who have not received prophylactic vitamin K at birth. The risk is increased in breastfed babies and in those with poor oral intake. The incidence in babies not receiving vitamin K supplementation has been estimated at 0.25–1.7%, depending on the study population (Tripp et al. 1995), although studies have shown that it may now be less common even in communities without routine prophylaxis (Hey 2003). Numerous studies have shown that classical VKDB is prevented by a single intramuscular dose of vitamin K at birth (reviewed in Puckett and Offringa 2000; van Winkel et al. 2008; Shearer 2009). Routine prophylactic vitamin K has been the subject of much controversy, which is briefly summarised below.

Late VKDB

This occurs after the first week of life, most often between 2 and 8 weeks after birth, although presentation after 15 weeks of age has been reported (Sutor et al. 1999). The characteristic presentation is of sudden intracranial haemorrhage in an otherwise well, breastfed term baby, or in babies with liver disease (e.g. biliary atresia; Ch. 29.2) or malabsorptive states. Late VKDB in healthy breastfed babies can be prevented either by a single intramuscular dose of vitamin K or by repeated oral doses of vitamin K over the first 6 weeks of life. However, babies with chronic liver disease or malabsorption are likely to require prolonged vitamin K supplementation.

In all forms of VKDB, clotting studies show a prolonged PT with normal platelets and fibrinogen; in severe deficiency, the APTT may also be prolonged. In the presence of a typical clinical history, further diagnostic tests are usually unnecessary and correction of the PT following vitamin K administration provides additional confirmation. If doubt remains, factor assays of the vitamin K-dependent factors and of the inactive form of factor II (decarboxyprothrombin: PIVKA II) can be used to confirm the diagnosis (British Committee for Standards in Haematology, Haemostasis and Thrombosis Task Force 2002). Treatment of VKDB depends on the severity of the bleeding. In mild cases, vitamin K (1 mg), which should be given intravenously or subcutaneously (not intramuscularly because of the risk of haematoma), should suffice, as this increases the levels of active vitamin K-dependent coagulation factors within a few hours; where there is significant bleeding, FFP may be given, in addition to vitamin K (British Committee for Standards in Haematology, Haemostasis and Thrombosis Task Force 2002).

Vitamin K prophylaxis

Guidelines for the prevention of early VKDB (i.e. due to maternal medication that interferes with vitamin K) are to give a single intramuscular injection of vitamin K at birth together with antenatal administration of oral vitamin K to the mother during the last 4 weeks of pregnancy (British Committee for Standards in Haematology, Haemostasis and Thrombosis Task Force 2002). For classical and late VKDB, there are several options. This is because, although vitamin K supplementation undoubtedly prevents classical and late VKDB, controversy surrounds the route of administration since the publication of studies by Golding et al. (1992), which suggested a link between intramuscular vitamin K at birth and later childhood malignancies. These studies have been criticised on methodological grounds (Brousson and Klein 1996), and at least nine further studies have since investigated this link (reviewed in Zipursky 1999; Puckett and Offringa 2000; Roman et al. 2002; van Winkel et al. 2008; Shearer 2009). Although seven studies failed to confirm the link with malignancy, two produced equivocal results, and the controversy is unlikely to be resolved unequivocally in the short term. There is no link between oral vitamin K and malignancy.

The current situation is perhaps best summarised by the Cochrane review (Puckett and Offringa 2000), which concludes:

- Intramuscular vitamin K has been proven to prevent classical disease.
- Oral vitamin K has been proven to improve biochemical parameters of vitamin K deficiency in the first week of life.
- The efficacy of oral supplementation in preventing late disease is unproven. This probably reflects the unpredictable absorption and difficulties with compliance with repeated doses of oral vitamin K.

Both the American Academy of Paediatrics and the Royal College of Paediatrics and Child Health recommend vitamin K

supplementation at birth. In healthy babies, the choice of administration route is increasingly being left to parents, who have to balance the remote risk of a borderline increase in leukaemia (odds ratio between 1.06 (confidence interval (CI) 0.89–1.25) and 1.16 (CI 0.97–1.39)) against the slightly higher risk of VKDB (2.7/100 000) in infants given various different oral vitamin K regimens. The best oral administration regimen has not yet been identified and is reviewed by Shearer (2009). It is clear that one or two oral doses is not sufficient and available data suggest that regimens employing a once-weekly or daily dose of vitamin K for the first 3 months of life are likely to be more effective (for example 2 mg at birth, followed by 1 mg weekly for 3 months, as used in Denmark, or 1 mg at birth followed by 25 µg daily for 3 months, as used in the Netherlands) (Shearer 2009).

Disseminated intravascular coagulation

The main precipitants of DIC in neonates are associated with severe hypoxia and/or acidosis and include peripartum haemorrhage, severe birth asphyxia, meconium aspiration and sepsis. The pathophysiology of DIC is complex and not fully understood. The process seems to be triggered by release of TF and cytokines from damaged endothelium and/or monocytes, which results in widespread activation of the coagulation cascade with subsequent consumption of clotting factors and a combination of thrombotic and haemorrhagic manifestations (Bick 2002). Clinically, DIC is seen in sick neonates and presents with generalised bleeding, including pulmonary haemorrhage and oozing from venepuncture sites. The usual pattern of coagulation abnormalities in DIC is prolongation of the PT, APTT and TT, together with low platelets and fibrinogen. D-dimers are increased but measurement is not necessary for diagnostic purposes and is often not done in neonates because of the need for an extra blood sample (results should also be interpreted with caution, as D-dimers are not specific and can be found in healthy neonates with no evidence of coagulopathy) (Karpatkin 1999). The most important aspect of management of DIC is treatment of the underlying cause. Blood product replacement is indicated for the treatment of clinical bleeding: FFP is a good source of procoagulant proteins as well as protein C, protein S and antithrombin; cryoprecipitate contains higher concentrations of factor VIII and fibrinogen and is useful when the fibrinogen levels are low (British Committee for Standards in Haematology, Haemostasis and Thrombosis Task Force 2002). There are no recent randomised trials that address optimum management of bleeding associated with neonatal DIC. However, a pragmatic approach is to aim to maintain the platelet count above $30 \times 10^9/l$ and the fibrinogen $>1 \text{ g/l}$. There is increasing experience of successfully using recombinant factor VIIa for neonates with bleeding unresponsive, or poorly responsive, to coagulation factor replacement with FFP and/or cryoprecipitate (reviewed and comprehensively referenced by Puetz et al. (2009)). Although there are some reports of an increased frequency of thrombotic events in neonates receiving factor VIIa, there is no evidence that this was directly due to factor VIIa administration rather than the underlying poor condition of the baby. The factor VIIa regimens used vary hugely; overall the most common dose used was 100 µg/kg every 2 hours (Puetz et al. 2009).

Other acquired coagulation disorders

Other causes of acquired coagulopathy in neonates include liver disease, metabolic disorders (e.g. hyperammonemia), extracorporeal membrane oxygenation and the consumptive coagulopathy with thrombocytopenia secondary to giant haemangioendotheliomas (Kasabach–Merritt syndrome) (Hall 2001).

Table 30.11 Causes of neonatal thrombocytopenia

Early (<72 hours)	Placental insufficiency (PET, IUGR, diabetes) NAITP Birth asphyxia Perinatal infection (group B <i>Streptococcus</i> , <i>Escherichia coli</i> , <i>Listeria</i>) Congenital infection (CMV, toxoplasmosis, rubella, coxsackie virus) Maternal autoimmune (ITP, SLE) Severe Rh HDN Thrombosis (renal vein, aortic) Aneuploidy (trisomy – 21, 18, 13)
Late (>72 hours)	Late-onset sepsis and necrotising enterocolitis Congenital infection (CMV, toxoplasmosis, rubella) Maternal autoimmune (ITP, SLE) Congenital/inherited (TAR, Wiskott–Aldrich)

PET, pre-eclamptic toxemia; IUGR, intrauterine growth restriction; NAITP, neonatal alloimmune thrombocytopenia; CMV, cytomegalovirus; ITP, idiopathic thrombocytopenic purpura; SLE, systemic lupus erythematosus; Rh, rhesus; HDN, haemolytic disease of the newborn; TAR, thrombocytopenia with absent radii.

Neonatal thrombocytopenia

Prevalence of neonatal thrombocytopenia

Thrombocytopenia (platelets $<150 \times 10^9/l$) is common in neonates. Several studies report a prevalence of thrombocytopenia of 1–5% of all newborns, around 10% of whom will have severe thrombocytopenia (platelets $<50 \times 10^9/l$). In neonatal intensive care units, thrombocytopenia develops in 22–35% of all admissions and in up to 50% of neonates who are preterm and sick (Roberts and Murray 2001).

Causes of neonatal thrombocytopenia

Conventional lists of the causes of thrombocytopenia include a large number of possible diagnoses, most of which are very rare. However, in routine clinical practice, it is more useful to be aware of the common causes and patterns of thrombocytopenia. Thrombocytopenia usually presents in one of two clinical patterns which reflect the most common causes: early thrombocytopenia (within 72 hours of birth) and late thrombocytopenia (after 72 hours of life). The principal causes of early and late thrombocytopenia are shown in Table 30.11.

Early thrombocytopenia

The most frequent causes of early thrombocytopenia in preterm infants are conditions resulting in fetal hypoxia. This thrombocytopenia is self-limiting, usually resolving within 10 days (Murray and Roberts 1996; Watts and Roberts 1999). It is seen in infants of mothers with pre-eclampsia, pregnancy-induced hypertension or diabetes; this form of thrombocytopenia is also seen in infants with IUGR (Murray and Roberts 1996; Watts and Roberts 1999). Thrombocytopenia is seen in virtually all such infants, although it is rarely severe (the platelet count usually remains above $50 \times 10^9/l$), except in neonates with severe IUGR. It is caused by reduced platelet production secondary to reduced megakaryocytopoiesis (this is

discussed in more detail below). The most important cause of severe early neonatal thrombocytopenia is neonatal alloimmune thrombocytopenia (NAITP), which is also discussed below.

Late thrombocytopenia
